Abstract

AIM: To investigate the potential associations among major depression, quality of life, and suicidal behavior in human immunodeficiency virus (HIV) patients.

METHODS: A detailed MEDLINE search was carried out to identify all articles and book chapters in English published from January 1995 to January 2015.

RESULTS: Based on the main findings, the prevalence of major depressive disorder (MDD) ranged from 14.0% to 27.2%. Furthermore, the prevalence of suicidal ideation varied from 13.6% to 31.0% whereas, attempted suicides were reported to range from 3.9% to 32.7%. Interestingly, various associated risk factors for both depression and suicide were identified in HIV patients. Finally, consistent associations were reported among MDD, suicidal ideation, and poor quality of life in individuals living with HIV.

CONCLUSION: Although additional studies are needed to elucidate this complex association, our results suggest the importance of early detection of both MDD and suicidality in patients living with HIV.

Key words: Major depression; Suicidal behavior; Quality of life; Human immunodeficiency virus infection

Core tip: Among patients with human immunodeficiency virus (HIV) the prevalence of major depressive disorder (MDD), suicidal ideation, and attempted suicides ranged from 14.0% to 27.2%, from 13.6% to 31.0%, and from 3.9% to 32.7%, respectively. Multiple risk factors for both depression and suicide were identified in HIV patients. Importantly, a consistent association has been reported between MDD, suicidal ideation, and poor quality of life in individuals living with HIV. The early detection and adequate treatment of depressive symptoms and suicidality should be considered fundamental tasks when managing HIV infected patients, particularly in those individuals who are severely medically ill.

INTRODUCTION

Chronic medical conditions such as human immunodeficiency virus (HIV) infection have been found to be associated with elevated stigma and discrimination, psychological distress, and poor social support[4]. Almost half of individuals diagnosed with HIV suffer from one or more comorbid psychiatric disorders[5] and experience a poorer health-related quality of life compared to individuals without comorbidities[6].

Major depressive disorder (MDD) is a highly comorbid psychiatric condition in patients with HIV, and the presence of MDD is associated with poor adherence to treatment, disease progression, and lower quality of life[6]. It has been well established that depressive symptoms may contribute to both HIV progression and mortality[3]. For example, in a 7-year longitudinal study, Ickovics et al[7] found that women with HIV and chronic depressive symptoms had twice the risk of dying by suicide compared to those with few or no depressive symptoms. Specifically, the mortality rates were 54% among patients with chronic depressive symptoms and 48% among those with intermittent depressive symptoms as compared to 21% for women having few or no depressive symptoms and low CD4 cell counts[6]. MDD is also associated with premature dropout and poorer outcomes after treatment[7,8], as well as persistent drug use in heroin users[9].

In addition to depression, suicidality, which includes both suicide ideation and attempts, is considered to be another major psychiatric problem associated with HIV/acquired immune deficiency syndrome (AIDS)[10]. Similar to MDD, an association between suicidality, poor quality of life, poor adherence to antiretroviral therapy, and non-disclosure of HIV status to significant others has been also reported[10,11]. Overall, socio-demographic variables (e.g., female gender, younger age); psychiatric conditions such as substance abuse, MDD, and a history of prior suicide attempts; neuropsychiatric side-effects of antiretroviral therapy and psychotropic medication; psychosocial factors including heterosexual orientation, poor social support, loss of employment, maltreatment, and sexual abuse; and clinical factors (e.g., stress reactions, the perception of pain, physical impairment, psychological/physical symptoms, and AIDS diagnosis) have been found to contribute to suicidality among HIV patients[12-19].

Thus, individuals with HIV infection may have a higher risk of suicide than those individuals without HIV[20-22]. In addition, many individuals living with HIV are reluctant to disclose their HIV serostatus to friends and/or family due to the fear of stigmatization[23,24]. Moreover, individuals who experience this type of fear may have disadvantages with regards to seeking HIV testing, education, or treatment[25].

Interestingly, the introduction of antiretroviral medications significantly improved both HIV health-outcomes and life expectancy of HIV infected patients, which led to a significant reduction of suicide rates[26]. However, patients living with HIV/AIDS are still dying in large numbers and, therefore, examining quality-of-life issues remains an important area of research[27]. In particular, individuals with HIV reported profound alterations in day-to-day activities, significant relationships, and health status[28]. Accordingly, several psychometric instruments and health questionnaires have been specifically developed to evaluate quality of life among individuals with HIV.

Based on the current literature, it remains unclear whether or not individuals with HIV and poor quality of life are at a higher risk of depression/suicidality than those with HIV and a higher quality of life. Thus, the present review aimed to investigate the nature of the associations between MDD, quality of life, and suicidal behavior in HIV patients.

MATERIALS AND METHODS

In order to provide a critical review of the associations among depression, suicidality, and quality of life among patients with HIV infection, we performed a detailed search using the largest existing databases (PubMed/ MEDLINE, Scopus, Web of Science, and Psychinfo) to identify all articles and book chapters in English published between January 1995 and January 2015. Specifically, the following search terms were used: “Major depression” OR “Major Depressive Disorder” OR “MDD” AND “Suicidal Behavior” OR “Suicide attempts” OR “Suicide ideation” OR “suicidality” AND “Quality of life” AND “HIV infection.”

Full-text articles were evaluated for relevance when a title or abstract appeared to describe a study eligible for inclusion. Abstracts that did not explicitly mention the association between depression, suicidality, and quality of life among individuals living with HIV were excluded. We also excluded meta-analytic studies and reviews. Overall, we identified 36 articles; however, only 12 full-text articles included in our review.
Study design and eligibility criteria
To achieve a high standard of reporting, we have adopted Preferred Reporting Items for Systematic Reviews and Meta-Analyses’ (PRISMA) guidelines[29]. The PRISMA Statement consists of a 27-item checklist and a four-phase flow diagram for reporting in systematic reviews. PRISMA includes the broader effort to improve the reporting of different types of health research as well as to improve the quality of research used in decision-making in healthcare.

RESULTS
Number of studies selected
The combined search strategy yielded a total of eighty articles of which, after a complete analysis, twenty-eight full-text articles were screened and fifty-two were excluded. We excluded articles that were not published in peer reviewed journals, those that were not in English language, articles without abstracts, abstracts that did not explicitly refer to the main topic, and those with unclear data regarding materials and methods and subjects which were analyzed. We assessed fourteen articles for eligibility but two full-text articles were excluded due to low-relevance to the main theme. Therefore, twelve articles fulfilled our inclusion criteria and were included in the present review (Figure 1).

Type of studies selected
Studies that investigated the prevalence of depression, suicide ideation, suicide thoughts, in patients living with HIV: Nine studies investigated the prevalence of suicide ideation/thoughts and associated risk factors in HIV infected patients. Ogundipe et al[30] found that 13.6% of 295 people living with HIV/AIDS (PLWHA) reported suicidal ideation.

Moreover, Kinyanda et al[31] demonstrated that the prevalence of moderate to high risk for suicidality (MHS) and lifetime suicide attempts of 618 recruited patients was 7.8% and 3.9%, respectively.

In a sample of 62 randomly selected HIV+ women, Lewis et al[32] investigated the existence and impact of major depression. The researchers also found that activities of daily living (ADL) and the subjective questionnaire of cognitive functioning were useful instruments to assess depression.

In another study, the clinical/behavioral characteristics of 71 patients in northern Taiwan as related to their HIV status have been explored by Lee et al[33]. Based on the main findings, anxiety was reported in 21.0% of patients, depression in 27.2%, memory alterations in 32.7%, and suicide attempts in 32.7%. Atkinson et al[34] also reported that HIV+ individuals (N = 203) reported a significantly higher rate of lifetime MDD than HIV- participants (14% vs 5%). However, both HIV+ and HIV- reported similar rates of current MDD.

Furthermore, Sherr et al[35] demonstrated that the prevalence of suicidal ideation was 31% in a sample of 778 patients living with HIV. Interestingly, heterosexual men and black respondents were twice as likely to experience suicidal ideation when compared to gay men or women and White/Asian respondents. In addition, individuals who did not disclose their HIV status were twice as likely to report suicidal ideation as compared to other subjects.

In another study conducted in a sample of 28 Chinese HIV+ participants and 23 matched HIV- controls, nearly 79% of HIV infected individuals had a significantly higher
lifetime rate of major depression relative to 4% of the comparison group\(^\text{[35]}\). Moreover, 18% of these patients reported active suicidal thoughts.

Haller and Miles\(^\text{[36]}\) also examined suicidality among 190 HIV+ participants and reported that 26% had suicidal thoughts within 30 d of hospitalization, 49% revealed that they had a suicide plan, and 48% indicated they had suicide intent. Further, individuals with suicidal ideation had predominantly MDD (64%).

Finally, Kalichman et al\(^\text{[37]}\) found that in a sample of individuals aged 45 or older and living with HIV/AIDS \((N = 113)\), 27% reported suicidal thoughts.

**Studies that investigated the associated risk factors in patients living with HIV:** Six studies investigated the relevance of associated risk factors in HIV infected patients. Ogundipe et al\(^\text{[38]}\) identified unemployment, emotional distress, religion, HIV status non-disclosure, and previous suicidal attempt as significant predictors of suicidal ideation in their sample. In another study, Kinyanda et al\(^\text{[31]}\) reported that significant unique predictors of MHS included female gender, increasing negative life events, a previous psychiatric history, and MDD.

Other articles focused on the importance of associated risk factors in patients diagnosed with HIV. For example, sexual intercourse without condoms during the six previous months were found more frequently in HIV-negative heroin users compared to HIV-positive heroin users\(^\text{[33]}\) whereas higher levels of physical and psychological symptoms independently predicted suicidal ideation\(^\text{[41]}\).

Furthermore, Haller and Miles\(^\text{[36]}\) suggested that individuals with MDD, dysthymia, substance abuse, thought disorders, post-traumatic stress disorder (PTSD), or borderline/avoidant personality disorders were more likely to report suicidality.

Interestingly, subjects with suicidal thoughts more frequently used escape and avoidance whereas positive-reappraisal coping strategies were used less frequently\(^\text{[37]}\). The authors\(^\text{[37]}\) demonstrated the existence of associations among suicidal thoughts and perceived poor social support from friends/family even after controlling for depression.

**Studies that analyzed the association between depression, suicidality and quality of life in HIV patients:** Eight of the included studies examined the associations between depression, suicidality and quality of life in samples of HIV patients. First, a significant association between suicidal ideation and being unmarried, poor medication and quality of life was found by Ogundipe et al\(^\text{[38]}\) in a sample of 295 PLWHA.

Furthermore, Pompili et al\(^\text{[39]}\) reported that HIV patients with a poorer health-related quality of life (HRQoL) had higher hopelessness levels (these subjects were at high suicide risk) and were more likely to have depression than those with a higher HRQoL. In addition, higher scores on all dimensions of the Temperament Evaluation of Memphis, Pisa, Paris and San Diego self-administered version (TEMPS-A) were reported in patients with a poorer HRQoL relative to those with higher HRQoL. Furthermore, Atkinson et al\(^\text{[40]}\) reported that 203 HIV+ were more likely to have a lifetime substance use diagnoses than HIV- participants (14% vs 6%). They also found that worse daily functioning and life quality as well as unemployment were independently predicted by both depression and HIV status.

Palliative care and quality-of-life issues are still two relevant areas of research in patients with advanced AIDS. Breitbart et al\(^\text{[39]}\) investigated the impact of treatment for depression on the desire for hastened death in a sample of 372 patients with advanced AIDS. They reported a significant association between desire for death and depression; also, desire for death was reduced in those patients who responded to antidepressants medications. However, nearly half of those individuals who received antidepressant medications and/or supportive psychotherapy or counseling showed little or no improvement in depressive symptoms. In another study, Jin et al\(^\text{[33]}\) found that worse daily functioning was independently predicted by both major depression and HIV+ status in a sample of 28 Chinese HIV+ participants and 23 matched HIV- controls.

Furthermore, in a sample of HIV-infected women directly after diagnosis, Krabbendam et al\(^\text{[40]}\) found that the women experienced strong emotions and quality of life impairment, suggesting that high emotional distress may be occurred in specific phases of HIV illness. In addition, Haller and Miles\(^\text{[36]}\) demonstrated a significant association between quality of life variables and suicide ideation in 190 HIV patients. Specifically, leisure/social and family/friends were strongly associated with suicidal ideation in their sample. Finally, higher emotional distress together with poorer HRQoL were found in a sample of individuals living with HIV-AIDS \((N = 113)\) who reported suicide thoughts as compared to those who had not considered suicide\(^\text{[37]}\) (Tables 1 and 2).

**DISCUSSION**

The present mini-review aimed to investigate the associations among MDD, quality of life, and suicidal behavior.

First, our findings indicated that the prevalence of a current MDD diagnosis varied from 14.0% to 27.2% according to the selected samples\(^\text{[33,34]}\), however, as high as 79% of HIV patients reported a lifetime diagnosis of MDD\(^\text{[31]}\); Second, the prevalence of suicidal ideation ranged from 13.6% to 31.0%; whereas, the prevalence of attempted suicide ranged from 3.9% to 32.7%\(^\text{[31,30,33,34]}\); Third, various associated risk factors for depression and suicide were found to be important in HIV patients\(^\text{[15,33,30,31,36,27]}\).

Other recent studies\(^\text{[41-43]}\) confirmed this high but more variable prevalence of MDD in HIV patients ranging between 18% to 81% at some stage of the illness according to the different populations which were investigated, the different study designs as well as the different diagnostic

criteria which were used.

As reported by Hirsch Allen et al[44], depression may be evaluated both dimensionally as well as categorically and this is the first source of variability.

In addition, MDD in HIV patients may vary according to several variables such as the population of interest, main research hypotheses as well as comparisons with other studies/populations. Importantly, depressive symptoms that do not meet diagnostic criteria may be also associated with significant psychosocial impairment and disability[46]. Moreover, the role of somatic symptoms related to depression may be frequently neglected in HIV infected patients due to their frequent overlapping with somatic complaints directly related to the disease.

Overall, clinicians should carefully consider that screening, diagnosing, and quantifying depressive symptoms represent three different but equally critical/challenging tasks when managing depressed HIV infected patients.

MDD often contributes to the negative psychological effects of HIV, increases emotional distress, and exerts a critical impact on adherence to treatment over time in HIV-infected individuals[45]. Clinicians encounter a challenging task in diagnosing MDD in HIV patients given the complex nature of this association. One of the most debated issues is whether or not MDD is a manifestation of HIV brain disorder or, conversely, MDD should be considered the primary disorder that may be exacerbated by the presence of

HIV. Interestingly, some authors hypothesized that MDD and its clinical presentation should be considered an adjustment reaction to the diagnosis of HIV infection\[43\].

Moreover, the presence of depression may significantly impair the number and activity of lymphocytes in HIV-positive patients dramatically reducing the role of natural killer cells, which increases the mortality in this population\[41,42,46\]. Del Guerra et al\[43\] have suggested that HIV may predispose patients to the onset of MDD through the interaction between the following neurobiological mechanisms: (1) Chronic increase of inflammatory cytokines and abnormal activation of microglia and astrocytes; (2) Consistent reduction of monoamine levels; (3) Neurotoxicity; and (4) Reduction of neurotrophic factors and subsequent impaired neuroplasticity processes, and psychosocial factors.

Our findings indicate a significant association between suicide ideation/thoughts and poor quality of life in HIV patients\[30,36,37,40\]. Moreover, results also suggest that depression was significantly associated with\[38,39\] or predicted a poor quality of life in HIV patients\[34,35\]. According to population-based studies\[47\], an higher prevalence of suicide in subjects with HIV may be found relative to the general population, and comorbid mood disorders may be identified in more than half of subjects. Among HIV infected individuals, those with AIDS were more likely to report current suicidal ideation, lifetime suicidal thoughts, and suicide plans compared to those without AIDS. This may be explained by the fact that individuals diagnosed with AIDS usually have a poorer HRQoL than those with HIV infection. Also, the presence of severe depressive symptoms in these patients was a significant predictor of daily functioning together with unemployment, and life quality\[34,48\]. Moreover, depressive symptoms may be independent predictors of significant impairment in daily functioning and quality of life regardless of the effects of HIV, as suggested by Jin et al\[81\]. The negative consequences of MDD on daily functioning and employment have also been found in previous studies\[80\]. Taken together, these findings suggest the clinical relevance of early detection and adequate MDD treatment, particularly in those individuals who are severely medically ill.

The present review should be considered in the light of limitations. First, some included studies may reflect the authors’ choice according to their expertise and may include small sample sizes, which limit the generalization of the findings; Second, most studies were cross-sectional in nature and did not allow for causal interpretations of the associations between depression, quality of life, and suicidality in HIV patients; Third, some studies predominantly investigated the presence of suicide ideation instead of considering the impact of prior suicide attempts on the quality of life of HIV patients; Fourth, some studies were limited by the possible underestimation of MDD and suicidal behavior rates given the use of self-reported psychometric instruments and the limited power of some analyses to find significant differences regarding the proportion of patients with depression and suicidality.

The prevalence of depression and suicidal ideation are consistent in patients with HIV, suggesting the importance of early detection for both these conditions in this population. Also, significant associations have been reported among MDD, suicidal ideation, and poor quality of life in HIV populations. However, further studies are necessary to elucidate this complex association.

**COMMENTS**

**Background**

It has been reported that individuals living with human immunodeficiency virus (HIV) are at risk for both depression and suicidality. Most of individuals diagnosed with HIV suffer from one or more comorbid psychiatric disorders and experience a poorer health-related quality of life compared to individuals without comorbidities.

**Research frontiers**

It is quite unclear whether or not subjects with HIV and poor quality of life are at higher risk of depression/suicidality compared with HIV and higher quality of life.

**Innovations and breakthroughs**

Among patients with HIV the prevalence of major depressive disorder (MDD), suicidal ideation, and attempted suicides ranged from 14.0% to 27.2%, from 13.6% to 31.0%, and from 3.9% to 32.7%, respectively. A significant association has been reported among MDD, suicidal ideation, and poor quality of life in HIV populations.

**Applications**

Further additional studies are needed to elucidate the exact nature of the association between MDD, suicidality, and quality of life in HIV patients. The early detection and adequate treatment of these conditions is absolutely recommended in clinical practice, in particular in those individuals who are severely medically ill.

**Terminology**

PRISMA: The PRISMA Statement consists of a 27-item checklist and a four-phase flow diagram for reporting in systematic reviews in the effort to improve the reporting of different types of health research and the quality of research used in decision-making in healthcare. Hopelessness: Hopelessness may be defined as a negative perspective concerning the future, loss of motivation, and expectations. Hopelessness predisposes patients with psychiatric disorders to suicidal behavior and has been identified as an important risk factor for suicide; TEMPS-A: (Temperament Evaluation of Memphis, Pisa, Paris and San Diego) The TEMPS-A is a self-rating questionnaire consisting of 109 items for men and 110 for women assessing subaffective trait expressions as they were conceptualized in Greek medicine and in German psychiatry.

**Peer-review**

The review has great clinical implication as well.
