Abstract The classical functions of bile acids include acting as detergents to facilitate the digestion and absorption of nutrients in the gut. In addition, bile acids also act as signaling molecules to regulate glucose homeostasis, lipid metabolism and energy expenditure. The signaling potential of bile acids in compartments such as the systemic circulation is regulated in part by an efficient enterohepatic circulation that functions to conserve and channel the pool of bile acids within the intestinal and hepatobiliary compartments. Changes in hepatobiliary and intestinal bile acid transport can alter the composition, size, and distribution of the bile acid pool. These alterations in turn can have significant effects on bile acid signaling and their downstream metabolic targets. This review discusses recent advances in our understanding of the inter-relationship between the enterohepatic cycling of bile acids and the metabolic consequences of signaling via bile acid-activated receptors, such as farnesoid X nuclear receptor (FXR) and the G-protein-coupled bile acid receptor (TGR5).
1. Introduction

Research over the past 80 years has yielded considerable insight into the role of bile acids in intestinal fat absorption, hepatic bile formation, and cholesterol homeostasis. However more recently, it has become apparent that bile acids also serve as signaling molecules with metabolic effects that extend beyond their control of hepatobiliary and intestinal function. This has generated considerable renewed interest in bile acids and their metabolism. Bile acids are steroid acids synthesized from cholesterol in the liver. Following their synthesis, bile acids are secreted into the small intestine, where they aid in digestion and absorption of lipids and other biliary constituents. Bile acids are then carried in the portal circulation back to the liver for uptake and re-secretion into bile. The process of intestinal absorption is very efficient and about 95% of the bile acids secreted into the small intestine are reclaimed. Those bile acids that escape absorption pass into the colon and can be eliminated in the feces. Specialized membrane transporters expressed on the apical and basolateral membranes of the hepatocyte and ileal enterocyte mediate the movement of charged plasma membrane-impermeant bile acids molecules across those cell barriers. For hepatocytes, the major transporters are the Na$^+$-taurocholate cotransporting polypeptide (NTCP; SLC10A1) and members of the organic anion transporting polypeptide (OATP) family (OATP1B1 and OATP1B3 in humans) on the sinusoidal membrane and the bile salt export pump (BSEP; ABCB11) on the canalicular membrane. For the ileal enterocyte, the major transporters are the apical sodium dependent bile acid transporter (ASBT; SLC10A2) on the brush border membrane and the heteromeric organic solute transporter alpha-beta (OSTα-OSTβ; SLC51A, SLC51B) on the basolateral membrane. In this paradigm, the ASBT and OSTα-OSTβ function as major gatekeepers for the intestinal compartment of the enterohepatic circulation of bile acids. However, in addition to being important for determining the fate of bile acids, i.e., their absorption versus their excretion in the feces, bile acid uptake by the ileal enterocyte is important for gut-liver signaling and regulation of bile acid synthesis. During transit through the ileal enterocyte, bile acids activate the nuclear receptor farnesoid X nuclear receptor (FXR), and increase transcription of the polypeptide hormone, fibroblast growth factor-19 (mouse ortholog, FGF15). FGF15/19 is then released from the intestine and travels to the liver where it signals through its cell surface receptor, a complex of the fibroblast growth factor receptor-4 (FGFR4) and its protein co-receptor β-Klotho, to repress transcription of the microsomal cytochrome P450 gene cholesterol 7a-hydroxylase (Cyp7a1) and inhibit hepatic bile acid synthesis. Although a major function of the FXR-FGF15/19 pathway is to control hepatic bile acid synthesis and prevent bile acid accumulation, there is also evidence that this pathway can impact lipid, carbohydrate, and energy metabolism. Bile acids are being viewed increasingly as metabolic regulators, and this has led to increased energy expenditure and metabolic rate. TGR5 activation in the colon (not shown) can also increase release of glucagon-like polypeptide-1 (GLP-1), leading to improved glucose disposition and increased insulin sensitivity.

2. Bile acid signaling pathways and metabolic regulation

2.1. Effects of hepatic FXR on metabolism

FXR was established as the primary bile acid nuclear receptor in 1999. Although expressed in a variety of tissues such as white adipose, kidney and adrenal, FXR is expressed at highest levels in the liver and intestine and is best known for its role in maintaining bile acid homeostasis. This is accomplished in part by regulating the expression of bile acid transporters such as BSEP, OSTα-OSTβ and NTCP, and the expression of transcription factors such as small heterodimer partner (SHP), which is involved in the repression of CYP7A1. However, FXR also regulates the metabolism of other lipids, either directly or indirectly via its effects on bile acid metabolism. For example, FXR-mediated repression of hepatic bile acid synthesis also reduces the catabolism and elimination of cholesterol as a result of the cholesterol-bile acid precursor-product relationship. Through such direct or indirect mechanisms, FXR has been associated with a myriad of effects on lipid metabolism. With regard to triglyceride metabolism, activation of FXR by the natural agonist cholic acid reduces hepatic triglyceride levels by decreasing sterol regulatory element binding protein-1c (SREBP1c)-stimulated lipogenesis in a mechanism involving SHP. These effects of FXR on SREBP1c expression and triglyceride synthesis may be mediated in part by the
peroxisome proliferator-activated receptor gamma coactivator 1 alpha (PGC1α)18. In humans, FXR can induce expression of the nuclear receptor peroxisome proliferator-activated receptor alpha (PPARα), a master regulator of fatty acid metabolism19. In this way, activation of FXR could lead to increased lipolysis, increased fatty acid oxidation, and decreased lipogenesis. FXR’s list of actions also encompasses effects on lipoprotein metabolism20. For example, studies have shown that FXR can affect plasma lipid transport by decreasing expression of the apolipoproteins (Apo) as ApoAI and ApoCII, and increasing ApoCIII; FXR also induces expression of the very low density lipoprotein (VLDL) receptor to contribute to lipoprotein clearance21-23.

In addition to its role in lipid metabolism, FXR may regulate glucose metabolism26,27. FXR induction of SHP expression can decrease expression of hepatocyte nuclear factor-4 alpha (HNF4α) targets such as the gluconeogenic genes glucose-6-phosphatase (G6Pase) and phosphoenolpyruvate carboxykinase (PEPCK)28. This may be accomplished in part by FXR modulation of hepatic PGC1α to repress expression of these gluconeogenic genes29. Activation of FXR also stimulates expression of pyruvate dehydrogenase kinase, which may further suppress glycolysis and enhance fatty acid oxidation30. Finally, activation of Akt and effects on insulin secretion and signaling by FXR suggest that multiple pathways may be mediating its effects on glucose metabolism31.

2.2. Effects of intestinal FXR on metabolism

FXR activation in the intestine, specifically the ileum, has a major role in bile acid homeostasis. FXR regulates expression of the ileal bile acid transporters, ASBT, OSTα-OSTβ, and the cytosolic ileal bile acid binding protein IBABP (FABP6)3. However in addition to control of bile acid flux and systemic exposure to bile acids, intestinally expressed FXR may affect metabolism via regulation of FGF15/19 production. Evidence indicates that the actions of FGF15/19 extend beyond its effects on bile acid metabolism, and include regulation of lipid and glucose metabolism11. For example, transgenic overexpression of FGF19 or treatment with recombinant FGF19 reduces adiposity and increases metabolic rate and levels of the satiety hormone leptin32. FGF19 has been shown to inhibit hepatic fatty acid synthesis by decreasing the expression of SREBP1c through indirect mechanisms33. It is also important to note that FGF19 can signal through FGF receptors in addition to FGFR4 are also able to elicit similar metabolic effects37,38. These studies suggest that multiple pathways may be mediating its effects on glucose metabolism31.

2.3. Effects of TGR5 on metabolism

TGR5 was identified as a bile acid-activated G-protein coupled receptor in 200312. With the growing appreciation of bile acids as signaling molecules, considerable study is being directed towards understanding the physiological functions of TGR513. For example, bile acid activation of TGR5 can regulate gallbladder filling, intestinal motility, and may have a role in bile acid-induced itch and the analgesia associated with cholestatic liver disease44-46. There are also metabolic effects associated with TGR5 signaling in brown adipose, muscle, and macrophages47. As with FXR, there is increasing interest in TGR5 as a potential therapeutic target for a variety of metabolic diseases12,13,47. For example, administration of the TGR5-selective synthetic agonist (INT-777) to mice attenuated diet-induced obesity and improved glucose tolerance48. The metabolic benefits may be due in part to increased metabolic rate and energy expenditure, secondary to TGR5-mediated increases in expression of deiodinase 2 (DIO2) and increased production of thyroid hormone (thyroxine, T4)49,50. These metabolic effects may also be mediated through bile acid activation of TGR5 on enterocriocline L-cell in the distal small intestine and colon. In that mechanism, TGR5 signals to increase production and release of GLP-1, the incretin hormone that promotes insulin sensitivity, and thereby improves glucose disposition51,52. Therapies targeting GLP-1 are currently used to treat diabetes, and strategies that augment GLP-1 production, half-life, or activity may have benefit in other disorders such as hepatic steatosis and cardiac hypertrophy53. Finally, it should be noted that bile acids signal through other receptors and pathways in addition to FXR and TGR5, and additional research is needed to understand their contribution to the metabolic effects of bile acids5,3,45,54.

3. Metabolic effects associated with altered intestinal absorption of bile acids

3.1. Bile acid sequestrants and bile acid transporter inhibitors

Emerging research examining the effects bile acid sequestrants (bile acid binding resins) suggests a metabolic benefit associated with blocking intestinal absorption of bile acid beyond its well-characterized plasma cholesterol-lowering actions55. Bile acid sequestrants were originally used to treat hypercholesterolemia and bile acid malabsorption in the 1960s55,56. Disruption of the enterohepatic circulation of bile acids by blocking their intestinal absorption stimulates hepatic de novo bile acid synthesis from cholesterol. The hepatic demand for cholesterol is met by increasing hepatic cholesterol synthesis and plasma clearance of lipoproteins such as low density lipoprotein (LDL)57. Although not widely used to treat hypercholesterolemia after introduction of the HMG CoA reductase inhibitors (statins), bile acid sequestrants operating through this mechanism had shown benefit with regard to lowering plasma cholesterol levels and reducing cardiovascular disease in studies such as the Lipid Research Clinics Coronary Primary Prevention Trial58. However, in addition to their plasma cholesterol lowering properties, there is evidence that bile acid sequestrants can improve glycemic control, and the underlying mechanisms of action are being explored59-61. Various mechanisms have been thus far been implicated. Decreasing bile acid enterohepatic cycling will reduce the pool of bile acids available for micellar solubilization of lipids in the intestinal lumen, and is predicted to reduce lipid absorption in the proximal small intestine.
Indeed, treatment with a bile acid sequestrant has been shown to increase the incorporation of sterols and fatty acids into bile and feces, and alter lipid metabolism through excretion\(^8\). In addition, by blocking the apical uptake of bile acid into the ileal enterocyte, bile acid sequestrants block activation of the FXR-FGF15/19 pathway. This will increase hepatic CYP7A1 expression and bile acid synthesis, altering the composition of the bile acid pool. In mouse models treated with a bile acid sequestrant, it has been proposed that the increased synthesis of bile acids via the CYP7A1 pathway increases entry of natural TGR5 agonists (such as cholic acid and cholic acid derivatives) into the systemic circulation. This leads to increased energy expenditure in muscle and brown adipose tissue\(^50\). Blocking intestinal absorption also increases the flux of bile acids into the colon and can increase the TGR5-mediated release of GLP-1, which would act to promote insulin sensitivity\(^{51,52}\). Not surprisingly, administration of a small molecule inhibitor of the ASBT has effects similar to those described for treatment with bile acid sequestrants or ASBT inhibitors\(^{66,67}\).

### 3.2. Knockout models of defective intestinal bile acid absorption

Although loss of either the ASBT or OST\(^{α}\)-OST\(^{β}\) transporters impairs intestinal bile acid absorption, characterization of the \(Ashb\) and \(Ost\(^{α}\)-\(Ost\(^{β}\)) null mice is beginning to reveal important phenotypic differences in bile acid homeostasis that could affect lipid and glucose metabolism\(^{68,69}\). For the parameters examined to date, the \(Ashb\) null mice display a similar metabolic phenotype to that described for treatment with bile acid sequestrants or ASBT inhibitors\(^{66}\). Inactivation of the ASBT increases hepatic CYP7A1 and also reduces SREBP1c, improving triglyceride metabolism. With induction of hepatic bile acid synthesis and an enhanced flux of bile acids into the colon, there is also the potential for increased activation of TGR5\(^{50,52}\). The phenotype of the \(Ost\) null model is more complicated. Bile acids are internalized by the ileocyte, but cannot exit the cell due to loss of \(Ost\). This leads to activation of the FXR-FGF15/19 pathway and subsequent repression of CYP7A1 expression and a decrease in bile acid synthesis\(^{72,70}\). Similar to the \(Ashb\) null model, there is a decrease in intestinal lipid absorption due to a reduction in the bile acid pool size. However, the potential for TGR5 activation is predicted to be less in the \(Ost\) null mice. Candidate mechanisms and predicted metabolic consequences of blocking ileal apical \textit{versus} basolateral bile acid transport are summarized in Fig. 2.
