OBJECTIVE—To examine β-cell function across a spectrum of glycemia among Asian Indians, a population experiencing type 2 diabetes development at young ages despite low BMI.

RESEARCH DESIGN AND METHODS—One thousand two hundred sixty-four individuals without known diabetes in the Diabetes Community Improvement Program in Chennai, India, had a 75-g oral glucose tolerance test, with glucose and insulin measured at 0, 30, and 120 min. Type 2 diabetes, isolated impaired fasting glucose (iIFG), isolated impaired glucose tolerance (iIGT), combined impaired fasting glucose and impaired glucose tolerance (iIGT), combined impaired fasting glucose and impaired glucose tolerance, and normal glucose tolerance (NTG) were defined by American Diabetes Association guidelines. Measures included insulin resistance and sensitivity (homeostasis model assessment of insulin resistance [HOMA-IR]), modified Matsuda Index, 1/fasting insulin and β-cell function (oral disposition index $= \Delta_{30-120} \text{glucose}_{30-120} / \Delta_{30-120} \text{insulin}_{30-120} \times 1/[\text{fasting insulin}])$.

RESULTS—Mean age was 44.2 years (SD, 9.3) and BMI 27.4 kg/m² (SD, 3.8); 341 individuals had NTG, 672 had iIFG, IGT, or IFG plus IGT, and 251 had diabetes. Patterns of insulin resistance or sensitivity were similar across glycemic categories. With mild dysglycemia, the absolute differences in age- and sex-adjusted oral disposition index (NTG vs. IIFG, 38%; NGT vs. IIGT, 32%) were greater than the differences in HOMA-IR (NTG vs. IFFG, 25%; NGT vs. IIGT, 23%; each $P < 0.0001$). Compared with NTG and adjusted for age, sex, BMI, waist circumference, and family history, the odds of mild dysglycemia were more significant per SD of oral disposition index (iIFG: odds ratio [OR], 0.36; 95% CI, 0.23–0.55; iIGT: OR, 0.37; 95% CI, 0.24–0.56) than per SD of HOMA-IR (iIFG: OR, 1.69; 95% CI, 1.23–2.33; iIGT: OR, 1.53; 95% CI, 1.11–2.11).

CONCLUSIONS—Asian Indians with mild dysglycemia have reduced β-cell function, regardless of age, adiposity, insulin sensitivity, or family history. Strategies in diabetes prevention should minimize loss of β-cell function.

Diabetes Care 36:2772–2778, 2013

Type 2 diabetes mellitus is a global problem, with 80% of all cases worldwide occurring in low- and middle-income countries (1). However, despite the increasing prevalence of type 2 diabetes, the etiology of the disease remains incompletely understood. Previously invoked as the driving feature of diabetes, increased insulin resistance can trigger increased insulin production to maintain normoglycemia and, over time, can strain β cells to the point at which insulin production is no longer adequate (2–4), i.e., “β-cell exhaustion.” Characteristics associated with insulin resistance, particularly older age, obesity, and physical inactivity, are strong risk factors for diabetes (5).

Yet, poor β-cell function also may have more of a primary role in diabetes development. The inadequate β-cell response to physiologic needs for insulin not only may be an acquired feature (e.g., as a result of insulin resistance) but also, at least in some individuals, may be an inherent feature. β-Cell dysfunction has been detected early in the pathogenesis of the disease (6), with recent cross-sectional and longitudinal studies detecting dysfunction in people with prediabetes or even normoglycemia (7–10). Supported by recent genetic discoveries (11); these studies suggest that some individuals have an underlying susceptibility to poor β-cell function (12) and that β-cell dysfunction may be an early driving metabolic feature of diabetes development.

Most studies of diabetes pathogenesis have been conducted in populations of European descent; however, more people have diabetes in other populations worldwide. Asian Indians, in particular, experience high rates of type 2 diabetes (13) at younger ages and lower BMI values (14) compared with other populations. They have high basal insulin levels (15) that are not entirely explained by obesity or adverse fat distribution (16), which are commonly cited factors related to insulin resistance. Considering these characteristics, Asian Indians may be an ideal population to utilize for developing a better understanding of the relative roles of β-cell function and insulin resistance in the pathogenesis of type 2 diabetes. Previous studies that have examined the etiology of diabetes in Asian Indians have produced conflicting findings. Altered β-cell function has been associated with impaired glucose tolerance (IGT) (17), has not been associated with IGT (18,19), and has been associated with impaired fasting glucose (IFG) but not IGT (20). Furthermore, β-cell function has not always been evaluated rigorously in Asian Indians (i.e., expressed relative to the insulin resistance of each individual) (21). We investigated the associations between the pathophysiologic mechanisms of insulin resistance and β-cell function with glycemic status in a large cohort ($n = 1,264$) of Asian Indians in Chennai, India.

RESEARCH DESIGN AND METHODS

Study population
Study subjects were individuals in the Diabetes Community Lifestyle Improvement Program, a primary prevention trial in Chennai (formerly Madras) testing the effects of a stepwise model of diabetes prevention, including a culturally tailored and intensive lifestyle intervention plus metformin when needed (22). Community-wide recruitment targeted men and women at large-scale community events, housing or apartment complexes, local businesses, places of worship, and educational institutions, through clinic records at the study site, and through direct referral by health care providers at the clinic. Community-based screening (n = 19,377) included a short survey, anthropometric measurements, and random capillary blood glucose test using a glucose meter (Lifescan; Johnson & Johnson, Milpitas, CA). Screened volunteers who were 20–65 years old with a random capillary blood glucose of ≥6.1 mmol/L (110 mg/dL) and without known type 2 diabetes were eligible for clinic-based screening (Diabetes Community Lifestyle Improvement Program baseline testing), which included a 75-g oral glucose tolerance test (OGTT) performed after an overnight fast.

Individuals who were pregnant, breastfeeding, with a history or evidence of heart disease, or with any other serious illness were excluded from the study. All subjects provided informed consent and participated in clinic-based screening between 2008 and 2011. Among the 1,285 individuals tested in clinic-based screening, 14 participants were excluded for missing glucose or insulin measures of the OGTT at any time point (i.e., 0, 30, or 120 min). An additional seven individuals were excluded for having negative or zero values of the insulinenic index (IGI), a measure of the early insulin response in the OGTT (23), calculated as the ratio of change in insulin to the change in glucose from 0 to 30 min (i.e., ΔI0–30/ΔG0–30). The final number of participants included in the present analyses was 1,264. The study was approved by the Emory University Institutional Review Board and the Madras Diabetes Research Foundation Ethics Committee.

Study procedures
Diabetes Community Lifestyle Improvement Program baseline testing included the collection of demographic, anthropometric, and glucose tolerance data (22). After fasting overnight for at least 8 h, subjects participated in a standard 75-g oral OGTT (24), with plasma glucose and insulin sampled at 0, 30, and 120 min. Other collected data included demographics, body weight, height, waist circumference, and family history of diabetes (defined as having one or more first-degree relatives with type 2 diabetes). For body weight assessment, subjects were asked to wear light clothing and weight was recorded after shoes and heavy jewelry were removed. Height was measured with a stadiometer to the nearest centimeter with subjects standing upright without shoes. BMI was calculated as mass (kg) divided by height squared (m²). Waist circumference was measured twice at the smallest horizontal girth between the costal margins and the iliac crests were measured at minimal respiration using a nonelastic measuring tape and averaged. OGTT samples were collected in EDTA, separated, and stored at −80°C. Plasma glucose (hexokinase method) was measured on a Hitachi 912 Autoanalyzer (Hitachi, Mannheim, Germany) using kits supplied by Roche Diagnostics (Mannheim, Germany). Insulin concentrations were estimated using an electrochemiluminescence method (COBAS E411; Roche Diagnostics, Mannheim, Germany). The intra-assay and interassay coefficients of variation for the biochemical assays ranged between 3.1 and 7.6%. Samples were processed in a laboratory accredited nationally by the National Accreditation Board for Testing and Calibration Laboratories and internationally by the College of American Pathologists.

Key variables
The glycemic status outcomes for this study were defined by the following American Diabetes Association criteria (25): diabetes as fasting plasma glucose ≥7.0 mmol/L (126 mg/dL) or 2-h postload glucose ≥11.1 mmol/L (200 mg/dL), or both; isolated IFG (IGF) as fasting plasma glucose 5.6–6.9 mmol/L (100–125 mg/dL) and 2-h postload glucose <7.8 mmol/L (140 mg/dL); isolated IGT (IGT) as 2-h postload glucose 7.8–11.0 mmol/L (140–199 mg/dL); NGT as fasting plasma glucose <5.6 mmol/L (100 mg/dL) and 2-h postload glucose <7.8 mmol/L (140 mg/dL); and combined IFG and IGT (IFG plus IGT) as fasting plasma glucose 5.6–6.9 mmol/L (100–125 mg/dL) and 2-h postload glucose 7.8–11.0 mmol/L (140–199 mg/dL). Prediabetes was defined as IIFG, IIGT, or IFG and IGT. Mild dysglycemia was defined as IIFG or IIGT.

The primary measure for β-cell function was the oral disposition index, denoted as DIₒ, calculated as follows as IGI adjusted for insulin sensitivity: DIₒ = (ΔIₒ–30/ΔGₒ–30 × [1/fasting insulin]) (23). Insulin resistance was estimated using homeostasis model assessment of insulin resistance (HOMA-IR; [fasting insulin × fasting glucose]/22.5) (26). The modified Matsuda Index for whole-body insulin sensitivity was calculated as follows: (10,000/square root of [fasting glucose × fasting insulin] × [mean glucose × mean insulin]), with mean glucose and mean insulin each calculated from values at 0, 30, and 120 min of the OGTT (27,28). Total area under the curve (AUC) for insulin and AUC for glucose were calculated using the trapezoidal rule, and a ratio of the two was created (AUCins/gluc). Secondary measures of β-cell function included the following: ([ΔIₒ–30/ΔGₒ–30] × [1/HOMA-IR]); ([ΔIₒ–30/ΔGₒ–30] × [modified Matsuda Index]); AUCinsulin/glucose × (1/fasting insulin); AUCinsulin/glucose × (1/HOMA-IR); and AUCinsulin/glucose × (modified Matsuda Index). Other covariates included BMI and waist circumference. Categories of overweight/obesity were those defined by the World Health Organization (29) both generically (25.0 ≤ BMI ≤ 30.0 kg/m² for overweight; BMI ≥ 30.0 kg/m² for obesity) and specifically for Asian populations (23.0 ≤ BMI ≤ 27.4 kg/m² for overweight; BMI ≥ 27.5 kg/m² for obesity). Waist circumference was categorized dichotomously, using waist ≥90 cm for men and ≥80 cm for women (30), and by tertiles.

Statistical analysis
Analyses were performed using SAS 9.3 (SAS Institute, Cary, NC). ANOVA allowed comparison of DIₒ across glycemic status categories, including the Tukey test for multiple comparisons. Non-normally distributed variables were log-transformed as required to meet assumptions of regression. A Score test was conducted to evaluate the possible use of ordinal logistic regression; the proportional odds could not be assumed as required (i.e., the null hypothesis that the model was constrained by the proportional odds assumption was rejected [χ² = 98.59; degrees of freedom = 3; P < 0.0001]).
### RESULTS

Table 1 provides baseline characteristics for the participants across glycemic status groups. Among all participants, the mean age was 44.2 years (9.3), and 37% were female. According to specific indices, 97.1 cm (SD, 8.5) and 88.6 cm (SD, 8.5) respectively. One-third had newly diagnosed diabetes (10.9%), more than half (21.9%) were obese, and 71.3% were overweight. According to BMI cut-points, 52% were female. According to specific indices, 97.1 cm (SD, 8.5) and 88.6 cm (SD, 8.5) respectively. One-third had newly diagnosed diabetes (10.9%), more than half (21.9%) were obese, and 71.3% were overweight. According to BMI cut-points, 52% were female. Data are mean and SD unless otherwise stated. *Geometric mean and geometric SD provided for DL and secondary measures of β-cell function.
A hyperbolic relationship was found between insulin sensitivity and insulin secretion. Using linear regression to estimate ln(IGI) as a function of ln(1/fasting insulin), the slope and its 95% CI for each glycemic category did not equal zero and were negative. For example, among individuals with diabetes, the slope of regression was $-0.8$ (95% CI, $-0.9$ to $-0.6$). Secondary measures of $b$-cell function also were evaluated for hyperbolic relationships between components. The hyperbolic relationship of IGI and $1/$HOMA-IR was poorer than IGI and $1/$fasting insulin; among those with diabetes, the slope of regression between IGI and $1/$HOMA-IR was $-0.46$ (95% CI, $-0.16$–$-0.0021$ vs. NGT). Across the same glycemic categories, HOMA-IR ($\text{mmol/l} \times \text{pmol/ln}$) was $15.29$, $18.52$, $18.02$, $21.98$, and $28.18$ (all $P < 0.0001$ vs. NGT). The modified Matsuda Index was negatively correlated with glycemic status exceeding that of HOMA-IR. For the measure $\text{AUC}_{\text{ins/glu}}$ of modified Matsuda, which exhibited the best hyperbolic relationship between insulin secretion and insulin sensitivity, $b$-cell function was independently associated with glycemic status (iIFG: OR, $0.11$; 95% CI, $0.07$–$0.16$; iIGT: OR, $0.34$; 95% CI, $0.25$–$0.46$) and HOMA-IR was not associated with glycemic status (iIFG: OR, $0.94$; 95% CI, $0.66$–$1.33$; iIGT: OR, $1.16$; 95% CI, $0.84$–$1.60$).

**CONCLUSIONS**—This study underscores the importance of $b$-cell dysfunction relative to insulin resistance across glycemic status groups in Asian Indians, particularly iIFG and iIGT. Using an index of $b$-cell function relative to insulin sensitivity, DIo, a highly significant difference in DIo was observed between NGT and iIFG or iIGT. A difference in insulin resistance, as measured by HOMA-IR, also was observed; however, the difference in mean HOMA-IR was greatest between iIFG plus IGT and diabetes, whereas the greatest difference in mean DIo was between NGT and iIFG.
### Reduced β-cell function and dysglycemia

from statistical modeling showed that the relative contributions of DIo to iIFG and to iIGT were greater than those of HOMA-IR, even after adjustment for variables known to impact disease development, including age, BMI, waist circumference, and family history of diabetes. These findings suggest that despite conflicting studies (17–20) in Asian Indians, a decrease in β-cell function may be a primary etiological factor in the development of type 2 diabetes in this ethnic group.

DIo was selected as the primary measure of β-cell function for several reasons. First, the measure agrees with the biological constructs known for β-cell function, because secretion of insulin is measured relative to the prevailing levels of insulin sensitivity in the body (21). Second, mathematical confirmation in studies with more rigorous designs has demonstrated a hyperbolic relationship of the two components (i.e., insulin secretion and insulin sensitivity) (23,32). Third, autocollinearity between the components of DIo is unlikely to drive the hyperbolic relationship, as described elsewhere (31). Fourth, longitudinal studies have indicated that DIo is a good measure of disease processes related to β-cell function, because it predicts the development of future diabetes (23). In addition to DIo, alternative measures of β-cell function were analyzed. Like another study, our results suggest that (AUCins/gluc × modified Matsuda Index) and (AUCins/gluc × fasting insulin) should be examined further as potentially strong measures of DIo (32). Across measures of β-cell function, similar findings indicated that the relative contribution of β-cell function toward glycemic status categories was greater than that of insulin resistance.

Studies that have examined β-cell function in various ethnic groups (i.e., β-cell function defined as insulin secretion with adjustment for insulin sensitivity within individuals) (12,21) have shown alternative patterns across glycemic phenotypes compared with those found in the current study. In a study of 1,399 normal-weight Japanese adults, those with iIFG were found to have somewhat preserved β-cell function using the ratio of change in AUC for plasma insulin to plasma glucose (ΔAUCins/ΔAUCpG) from 0 to 120 min of the OGTT after adjustment of the Matsuda Index. This measure of the disposition index was reduced in iIFG (mean ± SEM, 7.1 ± 0.5; P < 0.05; with iIFG defined as fasting plasma glucose 6.1–6.9 mmol/L) compared with the NGT group (9.7 ± 0.2). A more extreme and statistically significant difference was detected in the iIGT (mean ± SEM, 2.7 ± 0.2) and the combined IFG plus IGT (2.1 ± 0.2) groups compared with both the NGT and iIFG groups (P < 0.05) (33). In another study of 1,272 Chinese adults, a decline in early phase DIo (ΔAUCPG/ΔAUCpG at 30 min, adjusted with the Matsuda Index) was found in both iIFG (fasting glucose 5.6–7.0 mmol/L) and iIGT—both significantly lower than NGT—but DIo in iIGT was significantly lower than DIo in iIFG (both P < 0.05) (34). The current study showed that early-phase DIo was significantly reduced in iIFG as in iIGT. These findings are supported by the longitudinal Inter99 study involving Danish adults. Early-phase DIo was measured at both baseline and 3-year follow-up using fasting insulin, 30-min insulin, and 30-min plasma glucose adjusted for insulin sensitivity index (10). The authors reported that DIo was lower in those with incident iIFG and iFPG plus IGT than in those with incident iIFG (fasting plasma glucose 6.1–6.9 mmol/L) after 5 years of follow-up. However, among all individuals with NGT at baseline (n = 3,145), those who would later develop iFPG (NGT to iFPG) had lower mean DIo at baseline compared with those who would eventually develop iGT (NGT to iGT). These results suggest that individuals who develop iFPG already have significantly lower DIo in normoglycemia, and the reduction in DIo during normoglycemia may be as severe or more severe in those who eventually develop iFPG compared with iGT. In
populations in which the progression toward diabetes is particularly rapid, the level of DL, in normoglycemia may be an important factor related to disease risk. Future multiethnic studies are needed to determine if and how β-cell decline varies by ethnicity and to what degree differences lie between iIFG and iIGT.

This study has several important strengths. It contains a large, well-characterized, community-based sample stemming from the screening of almost 20,000 people and, therefore, was not limited to hospital- or clinic-based samples. All cases of diabetes were newly diagnosed. A hyperbolic relationship was found between insulin sensitivity and insulin secretion using linear regression to estimate ln(DL,0–30 / ΔG0–30) as a function of ln(1/fasting insulin), indicating appropriate use of the disposition index as a measure of β-cell function. We used standardized regression to enable comparison of variables that were measured in different units and, consequently, to directly compare the relative contributions of β-cell function and HOMA-IR to the development of prediabetes and diabetes.

The limitations of this study include its cross-sectional design, limiting further inquiry regarding temporality, and the degree of representation of the sample, because results may not be generalizable to other populations (e.g., other racial/ethnic groups). In addition, all subjects had a random blood glucose level of ≥6.1 mmol/L before receiving the OGTT and, therefore, the NGT group may not be representative of normoglycemia. However, if the NGT group had normal random blood glucose levels, even greater differences between NGT and iIFG or iIGT groups would be expected. Therefore, our results provide conservative estimates of the lower β-cell function and higher insulin resistance in iIFG and iIGT relative to NGT groups. We excluded seven individuals for having negative or zero values of the insulinogenic index, values considered biologically implausible; however, this number comprises a very small percentage of the total sample (0.5%), smaller than reported in another study (2.7%) (23). Only one OGTT test was performed for each participant, and thus the classification of some individuals may have changed if the OGTT had been performed a second time. Another limitation pertains to the use of an OGTT-derived measure of β-cell function, rather than estimates based on the glucose clamp technique or the frequently sampled intravenous glucose tolerance test as used by Bergman et al. (21), who showed that insulin secretion had a hyperbolic relationship (i.e., y = constant/x) with the existing state of insulin sensitivity. The findings here, using the measure of DL, for β-cell function, are consistent with several other studies that used euglycemic clamps and intravenous glucose tolerance tests. These studies have shown that poor insulin secretion begins sometime during normoglycemia (35, 36). Also, they have highlighted that potential differences in β-cell dysfunction may exist between IFG and IGT phenotypes (37–39), particularly that impairment of β-cell function may occur in iIFG at least as much as in iIGT.

Although the disposition index was originally based on intravenous sampling techniques, an OGTT-derived measure has been shown to be valid (23) and may include additional benefits in the study of β-cell function. The hyperbolic relationship between insulin sensitivity and insulin secretion has been demonstrated using OGTT data, indicating that DL, is a valid measure of β-cell function and is highly predictive of 10-year incidence of diabetes (23). Several metabolic factors, such as glucose disposition, differ between oral and intravenous glucose loads as related to different responses in the liver and in the periphery and, thus, OGTTs may probe important physiological processes in glucose metabolism that cannot be studied through intravenous testing. Finally, OGTTs are easy to perform in populations, making them more convenient for epidemiological studies in which recruitment of sufficiently large study samples can correct for within-subject variability (23, 31, 40). The minimum sample size needed to detect a 20% change when using the insulinogenic index is 181 (40), a number far exceeded by the sample size of the current study. Thus, DL, is a valid, informative, and practical approach to the study of β-cell function.

Using a robust measure of β-cell function, the current study provides evidence that those in any category of dysglycemia, including iIFG and iIGT, have lower β-cell function compared with those in the NGT category. This study also showed that insulin resistance was greater across all categories of dysglycemia compared with NGT. However, the relative contribution of insulin resistance was not as great as that of β-cell function in any given glycemic status group. As such, the primary prevention and control of diabetes will require strategies to preserve β-cell function and reduce β-cell decline.

In conclusion, our data demonstrate markedly reduced β-cell function among Asian Indians with mild dysglycemia. These abnormalities cannot be attributed to differences in age, adiposity, insulin sensitivity, or family history. Prospective studies are needed to further investigate the relative roles of β-cell dysfunction and insulin resistance in the early natural history of diabetes.
