COMMENTARY. Dramatic advances in next-generation sequencing technologies have led to a rapid increase in the amount of exome sequencing data, which has advanced our understanding of the genetic basis of neurologic diseases, including epilepsy. In recent years, a surprising number of missense mutations and deletions/truncations (>140) have been identified in NMDA receptors through whole exome sequencing [2]. These mutations are scattered across all domains in NMDA receptor subunits, including the GRIN1 gene, which encodes the GluN1 subunit. Moreover, these mutations appear associated with multiple neuropathological conditions, for which epilepsy/seizures comprise the largest group [2]. GRIN2A/GluN2A subunit constitutes a locus for mutations in a subset of patients with early-onset epilepsy [2]. This report suggests that the GRIN1/GluN1 subunit may be another locus for early-onset seizures.

Despite the identification of new NMDA receptor mutations, there are still only minimal functional data available for a handful of de novo mutations [2]. One noteworthy example is GluN2A(L812M), which was identified in a patient with intractable seizures and early-onset epileptic encephalopathy [3]. Functional studies of this mutation suggested that a profound increase in receptor function likely contributes to the patient’s phenotype. Evaluation of the potency of FDA-approved drugs that can block mutant NMDA receptors raised the possibility of personalized therapies. When the NMDA receptor channel blocker memantine was introduced into the treatment regimen for this patient, it significantly reduced seizure frequency [4]. While this effect remains to be replicated in other patients and rigorously tested in clinical trials, the example emphasizes the need and potential promise of functional analysis of the rapidly expanding list of NMDA receptor mutations revealed by gene sequencing programs for patients. Locations of the reported GRIN1 mutations were in pre-M1 helix (D552E), M3 transmembrane domain (M641I and N650K), and M4 transmembrane domain (G815R), all of which are considered as important elements/domains that are likely to influence NMDA receptor gating. We expect that future studies of the effects of these GRIN1 mutations on NMDA receptor functions will be useful not only for clarifying molecular mechanism underlying these patients’ phenotype, but also for exploring the potential targeted therapies.
