Summary

The embryonic thymus is colonized by the influx of hemopoietic progenitors in waves. To characterize the T cell progeny of the initial colonization waves, we used intravenous adoptive transfer of bone marrow progenitors into congenic embryos. The experiments were performed in birds because intravenous cell infusions can be performed more efficiently in avian than in mammalian embryos. Progenitor cells, which entered the vascularized thymus via interlobular venules in the capsular region and capillaries located at the corticomedullary junction, homed to the outer cortex to begin thymocyte differentiation. The kinetics of differentiation and emigration of the T cell progeny were analyzed for the first three waves of progenitors. Each progenitor wave gave rise to \( \gamma/\delta \) T cells \( 3 \) d earlier than \( \alpha/\beta \) T cells. Although the flow of T cell migration from the thymus was uninterrupted, distinct colonization and differentiation kinetics defined three successive waves of \( \gamma/\delta \) and \( \alpha/\beta \) T cells that depart sequentially the thymus en route to the periphery. Each wave of precursors rearranged all three TCR \( V_\gamma \) gene families, but displayed a variable repertoire. The data indicate a complex pattern of repertoire diversification by the progeny of founder thymocyte progenitors.

Comparative developmental studies have been informative with regard to the evolution of the immune system in vertebrates. Studies in chickens have contributed to the understanding of the hemopoietic stem cell origin of both myeloid and lymphoid T and B cell lineages (1, 2). This avian model has several advantages for the study of T and B cell lineages (1, 2). The understanding of the hemopoietic stem cell origin of the immune system in vertebrates. Studies in chickens have contributed to the understanding of the hemopoietic stem cell origin of both myeloid and lymphoid T and B cell lineages (1, 2).

The chick–quail model has been used to show homing of the thymocyte progenitors into the embryonic epithelial thymus in three discrete waves (4–8), the first of which begins in chicken embryos on E6.5, the second on E12, and the third around E18. Each wave of progenitor cell influx lasts for 1 or 2 d, and is followed by the transient production of thymocyte progeny (7, 8). The first wave of thymus colonization involves T cell progenitors from the paraaortic region (7, 8), whereas the second and third waves of thymocyte progenitors come from the bone marrow and express the c-kit and the hematopoietic cell adhesion molecules (9, 10). Using congenic chicken strains that differ in the ov alloantigen expressed on hematopoietic progenitors and T lineage cells, H.B19ov+ and H.B19ov−, we have examined chimeras created by grafting thymic lobes from an ov+ donor into thymectomized ov− recipients to show the gradual replacement of donor thymocytes by ov− host thymocytes and their progeny. These experiments indicated that a series of waves or stream of thymocyte progenitors continually enter the thymus after hatching (11–13).

The ontogeny of chick T lineage cells can be monitored with anti-TCR monoclonal antibodies and molecular probes for the different TCR chains (14–16). At E12, \( \approx 5 \) d after the initial influx of thymocyte precursors, a subpopulation of thymocytes begins to express the TCR -\( \gamma/\delta \)-CD3 complex on their surface (17). These reach peak numbers on the circulation to colonize the spleen, yolk sac, and, finally, the bone marrow.

These experiments indicated that a series of waves or stream of thymocyte progenitors continually enter the thymus after hatching (11–13).
tions were generated sequentially in the first wave, but not
H.B19ov and CDR3 created by the V genes indicates that all of the different V
pressed by their progeny in the thymus, spleen, and intesti-
eral waves. Irrespective of the wave of embryonic progenitors (8).

Thymocyte transfer experiments in congenic chick strains indicate that the \( \gamma/\delta \) and (V\( \beta 1 \)) \( \alpha/\beta \) thymocytes generated by the different thymocyte progenitor waves colonize the peripheral lymphoid organs in discrete waves (11–13, 21). Examination of the TCR V\( \beta 1 \) repertoire generated by each wave of thymocyte progenitors and expressed by their progeny in the thymus, spleen, and intestines indicates that all of the different V\( \beta 1 \) gene segments are expressed as early as E17. The thymic V\( \beta 1 \)-D\( \beta 1 \)-J\( \beta 1 \) repertoire expressed by each of the three waves of hemopoietic progenitors includes the same V\( \beta 1 \) and J\( \beta 1 \) elements, and CDR3 created by the V\( \beta 1 \)-D\( \beta 1 \)-J\( \beta 1 \) junctions of similar lengths (13). The spleen is colonized both by V\( \beta 1 \) and V\( \beta 2 \) T cells, whereas it is difficult to find V\( \beta 2 \) T cells in the intestines (13, 20).

TCR-\( \gamma \) genes have been identified recently in the chicken. These include three V\( \gamma \) families, three J\( \gamma \) segments, and one C\( \gamma \) region (15, 16). Although ontogenetic studies in mice indicate that TCR-\( \gamma \) gene rearrangement proceeds in waves with \( \gamma/\delta \) T cells expressing the different V\( \gamma \) gene segments are generated sequentially (22–25), pilot studies in the chicken suggested that TCR-\( \gamma \) rearrangement may not be so tightly regulated during avian development (16). In the present study, we have examined the potential of each wave of embryonic progenitors to produce TCR-\( \gamma/\delta \) and TCR-\( \alpha/\beta \) (V\( \beta 1 \)) thymocytes by adoptive transfer of hemopoietic progenitors into congenic embryos. The ov alloantigen marker was used to purify the thymocyte progeny from the individual waves of progenitors colonizing the thymus. Repertoire analysis demonstrated that although the precursors of each wave rearrange all V\( \gamma \) and all J\( \gamma \) usage. The sequential differentiation of \( \gamma/\delta \) and \( \alpha/\beta \) T cells was a constant feature of all three developmental waves. Irrespective of the wave of progenitor colonizion the \( \gamma/\delta \) T cell progeny differentiated about 3 d faster than the \( \alpha/\beta \) T cell progeny. Likewise, the migration of \( \gamma/\delta \) and \( \alpha/\beta \) T cells was found to occur to an alternating fashion during each migration wave from the thymus to the periphery.

Materials and Methods

Animals. Embryonated eggs from the H.B19 strain of White Leghorn chickens were produced at the Institute Chicken Facility (Gipf-Oberfrick, Switzerland). Fertilized eggs were incubated at 38°C and 80% humidity in a ventilated incubator. The H.B19 strain was subdivided into two congenic lines, H.B19ov\( ^+ \) and H.B19ov\( ^- \), distinguished by the ov antigen present on T lineage cells in H.B19ov\( ^+ \) animals. The ov antigen, which is also expressed on bone marrow cells and a B cell subset, is recognized by the 11-A-9 monoclonal antibody (9, 26, 27).

Immunolabeling. The ov, TCR-\( \gamma/\delta \) and TCR V\( \beta 1 \) antigens were detected by the 11-A-9, TCR 1, and TCR 2 mAbs, respectively (17, 19, 26, 28). 11-A-9 is a mouse IgM and TCR 1 and TCR 2 are mouse IgG\( _2 \) antibodies. Second step antibodies were fluorescein labeled, sheep anti-mouse IgM and phycoerythrin- or Texas red-coupled anti–mouse IgG1 antibodies (Southern Biotechnology Assoc., Birmingham, AL). Controls were performed using the second step antibodies alone and regular staining of tissues from noninjected individuals of the H.B19ov\( ^- \) strain. Recent thymocyte emigrants, detected in blood by their FITC staining, were labeled by phycoerythrin-coupled TCR 1 or TCR 2 antibodies (Southern Biotechnology Assoc.). Frozen sections of embryonic organs were cut to a thickness of 5 \( \mu m \) on a cryostat (Bright, Hunkingdom, UK), fixed with acetone, and rehydrated in PBS containing 1% BSA.

Injection of Lymphoid Cells into Congenic Chickens. Adoptive transfer between H.B19ov\( ^+ \) and H.B19ov\( ^- \) strains could be performed without complications since these strains do not differ at major histocompatibility antigens and T cell alloreactivity against a different ov antigenic determinant has not been observed in mixed lymphocyte reaction and graft versus host reactions. Bone marrow cells (2.0 \( \times 10^7 \)) from donor H.B19ov\( ^+ \) embryos were injected into a large vein near the airsac of recipient H.B19ov\( ^- \) embryos (29). T these experiments were performed with E13 and E18 age-matched donor and recipient embryos. Control injections of sorted TCR-positive populations of E18 bone marrow cells were performed to determine that differentiated bone marrow lymphocytes were not able to colonize the thymus in this assay. For that purpose, bone marrow cells from 18-d-old H.B19ov\( ^+ \) embryos were suspended in PBS containing 10% FCS, filtered through a nylon sieve (mesh width of 25 \( \mu m \); Nytal P-25 my; SST, Thal, Switzerland) and centrifuged at 225 g for 7 min. Immunofluorescence staining was performed in 96-well plates, to avoid repeated centrifugation using either the anti–TCR-\( \gamma/\delta \) antibody TCR 1 or the anti-TCR V\( \beta 1 \) antibody TCR2 and then fluorescein-coupled anti-mouse Ig antibody (Silenus, Hawthorn, Australia). Stained and unstained bone marrow cells were resuspended in 10% FCS/PBS and sorted using a FACSTAR Plus\( ^\text{R} \) cell sorter (Becton Dickinson, Mountain View, CA). None of the recipients received irradiation or other immunosuppressive treatment. Donor ov\( ^+ \) cells in the thymus were analyzed by flow cytometry and by two-color immunofluorescence staining of frozen tissue sections. For analysis by FACScan\( ^\text{R} \), single thymocyte suspensions were made by physical disruption in PBS and filtration through a nylon sieve.

To analyze the TCR-\( \gamma \) repertoires specifically generated by E13 and E18 bone marrow precursors, \( \gamma/\delta \) thymocytes of the donor type were sorted 9 d after injection of the precursors. Thymocytes were sorted by FACS into two-color immunofluorescence staining using the anti–TCR-\( \gamma/\delta \) antibody TCR 1 and the anti-ov antibody 11-A-9 and then FITC-coupled anti–mouse IgM and phycoerythrin-coupled anti–mouse IgG1 antibodies (Southern Biotechnology Assoc.). The cells were sorted using a FACSTAR Plus\( ^\text{R} \) cell sorter.

Analysis of Recent Thymocyte Emigrants. Emigration of the thymocytes into the circulation was examined after in situ FITC labeling of thymocytes. Young chicks were anesthetized by intramuscular injection of 0.4 ml ketamin solution (Imalgene 500; Rhone Mérieux, Lyon, France; diluted 1:10 in PBS) followed by a short inhalation of Halothane (Hoechst, Frankfurt, Germany). The skin of the neck region was opened with scissors and each thymus lobe was injected with 10 \( \mu l \) of an FITC solution at 1...
mM in DM SO. The skin was then closed using tissue clamps (Autoclip; Clay Adams, Becton Dickinson Primary Care, Sparks, MD) and the chickens were kept warm under an infrared lamp until they were fully conscious. Chickens were bled 12 h after injection and FITC-labeled lymphocytes were analyzed by flow cytometry.

**cdNa Synthesis**. Total cellular RNA from thymus was isolated using the guanidium isothiocyanate method (30). About 5 µg was used as template for the synthesis of randomly primed single-stranded cdNA using mouse mammary leukemia virus reverse transcriptase (Life Technologies, Inc., Gaithersburg, MD) in a reaction volume of 20 µl according to the supplier's instructions. This cdNA was subsequently diluted to 100 µl with water and heated to 94°C for 2 min to inactivate the mouse leukemia virus reverse transcriptase.

**PCR and Semiquantitative PCR** of Vγ transcripts. A PCR technique was used to amplify the TCR-γ transcripts. Transcripts deriving from rearranged TCR Vγ1, Vγ2, and Vγ3 genes were amplified independently using oligonucleotide primers specific for each Vγ family and a primer located in the Cγ region. Oligonucleotide primers CKVG1UP1, CKVG2UP3, and CKVG3UP1 were specific for the Vγ1, Vγ2, and Vγ3 regions, respectively. The CKCG1D01 oligonucleotide primer was located 230 nucleotides downstream the 5' end of the Cγ region. The procedures used for semiquantitative PCR followed the detailed description given by Keller et al. (31). The amount of cdNA synthesized was calibrated by using the relative expression level of β actin as a standard. The two actin oligonucleotide primers 4611 and 4612, generated a band of 283 and 648 bp on cdNA and genomic DNA respectively (32). The following are CKVG1UP1 (Vγ1 region): GCTACCAGAGAGAGAGT GCC; CKVG2UP3 (Vγ2 region): CATACAGGCCCTGTAT C; CKVG3UP1 (Vγ3 region): GATACTGTACATGTCTGG; CKCG1D01 (Cγ region, antisense): TTTTCATGCTTCTTCTCG; 4611 (5' of actin, from nucleotide 2057, see reference 32): TACCAAAATGATCCCGC; 4612 (3' of actin, from nucleotide 2704, antisense, see reference 32): CCTGCTTTGTGTTATGGC.

PCR reactions were in 30 µl using 1 U of Taq polymerase (Perkin-Elmer Cetus, Norwalk, CT). PCR buffer was prepared as suggested by Perkin-Elmer, but with the addition of 10 mM β mercaptoethanol. Reaction mixtures were denatured by heating to 96°C for 5 min, and then subjected to 32 rounds of amplification using a Biometra T.I.R.-thermoblock thermocycler under the following conditions: 96°C for 15 s, 50°C for 40 s, and 72°C for 1 min for cdNA amplification. Final extension was done at 72°C for 10 min.

**Cloning and Sequencing of TCR-γ Transcripts**. The TCR-γ Vγ-J-C regions were specifically amplified by PCR. Amplified DNA fragments were gel purified and cloned into pcR™II vector (Invitrogen, CA, CA). Sequences were determined from denatured double-stranded recombinant plasmid DNA (33) using Sequenase™ (Amersham Corp., Arlington Heights, IL) in the chain termination reaction (34) and the oligonucleotide primer CGAMMA1D1D starting 60 nucleotides downstream the 5' end of Cγ segment in the antisense orientation. In a number of cases where ambiguities remained, several additional nucleotide primers were used. Sequences were analyzed and assembled with the software package of the CITI2 (Paris, France). TCR-γ cdNA sequences have been submitted to the EM BL/GenBank / DDBJ database under accession numbers z97216 to z97332.

**Results**

Pathways of Tymocyte Precursor Migration into the Embryonic Thymus. The initial wave of progenitor colonization and thymocyte differentiation can be examined in situ in unmanipulated animals. However, analysis of members of the succeeding waves requires a discriminating strategy. Embryonic hematopoietic precursors express the ov antigen in H.B19ov+ birds, and the antigen is maintained on T lineage cells and a subset of B cells. This expression pattern allowed us to examine successive waves of the ov+ progenitor populations in the embryonic thymus and the fate of their T cell progeny in ov− congenic recipients. To examine the second wave of thymus colonization by progenitor cells, E13 bone marrow cells of the ov+ strain were injected into E13 chicken embryos of the congenic H.B19ov− strain, and the thymocyte progenitor influx, migration, and differentiation patterns were examined in thymus sections by immunohistochemistry. By E16, donor cells of bone marrow origin accumulated in the thymic blood vessels, both in interlobular venules and in capillaries located at the corticomedullary junction (Fig. 1); relatively few donor cells were found in the parenchyma of the thymus at this time. E19 ov+ cell invasion and accumulation within the thymic cortex was evident, but by E20 the donor cells had relocated to occupy the outermost cortex of the thymic lobules. This ontogenetic pattern suggests that thymocyte progenitors entering the embryonic thymus either via the corticomedullary junction or the capillary subsequently make their way to the outer cortex of the thymus (Fig. 1 C). The donor cells were later found throughout the cortex and by day 23, mature ov+ donor cells hadbegun to accumulate in the medulla. This complex intrathymic pattern of migration appears specific to bone marrow–derived thymocyte progenitors, since mature thymocytes and T cells failed to home to the thymus in other adoptive transfer experiments (not shown).

Intrathymic Differentiation Kinetics Are Consistently Accelerated for the γδ T Cell Subpopulation. The appearance of γδ T cells precedes that of Vγ1b/β cells by a period of ~3 d during the initial wave of thymocyte development (18), but studies in chick–quail chimeras suggest this may be a one time occurrence (8). In our studies of the second wave of thymocyte differentiation, the injection of E13 H.B19ov+ bone marrow cells into E13 H.B19ov− embryos led to the appearance of donor γδ Tocytes 5 d later and donor α/β thymocytes ~8 d later (Figs. 2 and 3 A). The proportion of ov+ donor thymocytes expressing TCR-γ/δ peaked at 40% on day 21. The first donor α/β (Vβ1+) thymocytes were detected on E20 and these reached a peak level of 57% on E26 (Fig. 3 A). When the third wave of thymocyte differentiation was examined by injection of E18 ov+ bone marrow cells into E18 ov− recipients, the same rule held true; γδ T cells appeared 4 d before the α/β T cells (Fig. 3 B). Interestingly, for the cell transfer experiments performed during the second wave of precursor colonization, the level of chimeraism was relatively greater for γδ than for α/β T cells (Fig. 3 C). However, taking into account the proliferation kinetics for the progeny of each precursor wave, the TCR-γδ thymocyte progeny appeared to be 12 to 16 times less numerous than the TCR-α/β (Vβ1) thymocyte progeny (Fig. 3 D, and...
Figure 1. Migration pathways of thymocyte progenitors. Thymus sections from E13 H.819ov− embryos injected with donor E13 H.819ov+ bone marrow cells were examined by differential immunofluorescence staining at E16, E19, E20, and E23. Donor ov+ progenitors are labeled with fluorescein; TCR-γδ and TCR-αβ-positive cells are labeled with Texas red. Original magnifications: (A) 270, (B) 170. Scale bars correspond to 100 μm. (C) Diagrammatic representation of chicken T cell progenitor migration pathways in the thymus. At E16, T cell progenitors were located either in capillaries at...
data not shown). The levels of donor \(\gamma/\delta\) and \(\alpha/\beta\) thymocytes peaked at days 23 and 26, respectively, corresponding to the main period of second wave emigration to the periphery. The differential chimerism of \(\gamma/\delta\) and \(\alpha/\beta\) T cells thus may reflect the differential emigration kinetics of \(\gamma/\delta\) and \(\alpha/\beta\) T cells.

Mature \(\gamma/\delta\) and \(\alpha/\beta\) T lymphocytes migrate to the periphery in alternating waves. The colonization of the thymus in discrete waves (7, 8), and the differences in differentiation and emigration kinetics of \(\gamma/\delta\) and \(\alpha/\beta\) thymocytes suggest interspersed emigration of the mature \(\gamma/\delta\) and \(\alpha/\beta\) thymocyte subsets (11-13). To test this hypothesis, we examined the phenotype of recent thymocyte migrants at different developmental ages. In these experiments, thymocytes of chicks at 21 (hatching)-30 d were labeled in situ by intrathymic injection of FITC. Blood samples were obtained 12 h later and labeled lymphocytes in the circulation were analyzed for expression of TCR-\(\gamma/\delta\) or TCR-\(\alpha/\beta\) (V\(\beta\)1) (Fig. 4). The FITC-labeled cells represented 3-10% of the peripheral blood lymphocytes. Approximately 75% of these were \(\gamma/\delta\) or \(\alpha/\beta\) (V\(\beta\)1\(^+\)) T cells; of the remaining 25% approximately half were \(\alpha/\beta\) (V\(\beta\)2\(^+\)) T cells and the rest were TCR\(^-\). Peaks of recent \(\gamma/\delta\) thymocyte emigrants were detected on days 21-23 and 27-28, and a peak of recent \(\alpha/\beta\) thymocyte emigrants was observed on days 24-26. The frequency of FITC-labeled \(\gamma/\delta\) thymocyte emigrants reached a maximum of 20%, whereas the peak of labeled V\(\beta\)1 emigrants reached a maximum of 70%. These figures reflected the fact that each precursor wave gives rise to \(\sim 5\% \gamma/\delta \) and 75% \(\alpha/\beta\) (V\(\beta\)1\(^-\)) thymocytes, respectively. Thymocyte progenitors in each colonization period thus gave rise to \(\gamma/\delta\) T cell progeny within 9 d and \(\alpha/\beta\) (V\(\beta\)1\(^+\)) T cell progeny within 12 d, and these migrated in the same sequence to the periphery.
recipients were analyzed by immunofluorescence flow cytometry: ov, for T cell expression as a function of developmental age. Thymocytes of the gated thymocyte population. Hatching occurs at E21.

Since each colonization period is followed by a refractory interval of ~4 d, the end result is alternating emigrant waves of γ/δ and α/β (Vβ1) T cells, with minimal overlap of migrant cells representing each of the three embryonic waves of thymocyte progenitors.

Each T thymocyte progenitor wave was addressed in these experiments. Simple sorting of E13 thymocytes reactive with the anti-TCR-γ/δ antibody was sufficient to isolate first wave progeny for repertoire analysis. Since the progeny of successive waves may accumulate in the thymus during development, isolation of the second and the third wave progeny required the more complex strategy of adoptive transfer between the H.B19ov+ congenic chicken strains. The progeny of second wave progenitors was isolated after the injection of E13 bone marrow cells into E13 H.B19ov+ embryos, and for analysis of the third wave, E18 H.B19ov+ bone marrow cells were injected into E18 H.B19ov+ embryos (injections of 2.0 × 10⁷ cells).

Since each colonization period is followed by a refractory interval of ~4 d, the end result is alternating emigrant waves of γ/δ and α/β (Vβ1) T cells, with minimal overlap of migrant cells representing each of the three embryonic waves of thymocyte progenitors. After adoptive transfer of E13 H.B19ov+ bone marrow (2.0 × 10⁶ cells) into E13 H.B19ov+ embryos, the donor cells were examined for T cell expression as a function of developmental age. Thymocytes of recipients were analyzed by immunofluorescence flow cytometry: ov, TCR-γ/δ and ov, and TCR Vβ1. Each dot plot presents 50,000 events for the gated thymocyte population. Hatching occurs at E21.

Figure 2. Differentiation kinetics of the second wave of thymocyte progenitors. After adoptive transfer of E13 H.B19ov+ bone marrow (2.0 × 10⁶ cells) into E13 H.B19ov+ embryos, the donor cells were examined for T cell expression as a function of developmental age. Thymocytes of recipients were analyzed by immunofluorescence flow cytometry: ov, TCR-γ/δ and ov, and TCR Vβ1. Each dot plot presents 50,000 events for the gated thymocyte population. Hatching occurs at E21.

Figure 3. Comparative differentiation kinetics of the second and third waves of thymocyte progenitors appearance of TCR-γ/δ and TCR-α/β (Vβ1) T cell progeny. (A and B) Proportion of thymocytes expressing TCR-γ/δ or TCR-α/β (Vβ1) among donor ov+ thymocytes was determined by immunofluorescence flow cytometry. Each point corresponds to the mean value for three to five animals in four independent experiments. The differentiation of second wave T cell progenitors was analyzed by adoptive transfer of E13 H.B19ov+ bone marrow into E13 H.B19ov+ embryos, and for analysis of the third wave, E18 H.B19ov+ bone marrow cells were injected into E18 H.B19ov+ embryos (injections of 2.0 × 10⁷ cells). (C) Proportions of donor ov+ thymocytes that express TCR-γ/δ or TCR-α/β (Vβ1) during the differentiation of the second wave of progenitors. (D) Proportions of donor ov+ TCR-γ/δ and ov+ TCR-α/β (Vβ1)+ thymocytes derived from second wave thymocyte progenitors among the total thymocyte population in the recipient. The realistic efficiency of the γ/δ and Vβ1 T cell differentiation pathways followed by the progeny of the second wave of thymocyte progenitors can be estimated, since the areas under these curves are roughly proportional to the numbers of γ/δ and Vβ1 thymocytes produced by the donor second wave progenitors. This assessment suggests that the donor progenitors produced ~15 times more α/β (Vβ1) than γ/δ thymocytes.
V\(\gamma\)3 gene segments were weakly represented. In contrast, V\(\gamma\)1, V\(\gamma\)2, and V\(\gamma\)3 transcripts appeared to be equally well represented in the first and the third thymus colonization (Fig. 5 B).

A more detailed analysis of the representative TCR-\(\gamma\) repertoires was performed by cloning of the PCR products and sequencing \(\sim 30\) clones for each V\(\gamma\) gene subfamily/thymocyte wave (Figs. 6 and 7). In the H.B19ov\(^+\) chicken strain, six V\(\gamma\)1, 12 V\(\gamma\)2, and 10 V\(\gamma\)3 members were detected. The V\(\gamma\)2 subfamily was divided into eight V\(\gamma\)2a members, three V\(\gamma\)2b members, and a new member, V\(\gamma\)2c, that differs significantly from the V\(\gamma\)2a and V\(\gamma\)2b subfamilies. In contrast to the differences in V\(\gamma\) subfamily usage (Fig. 5 B), significant differences were not seen in the representation of members within each V\(\gamma\) subfamily for the three thymocyte waves (Fig. 7). Different members of the three V\(\gamma\) families were found to rearrange with all three different J\(\gamma\) segments. However, preferential pairings of V\(\gamma\) and J\(\gamma\) segments were observed. In each of developmental waves, V\(\gamma\)2 segments were rearranged with J\(\gamma\)2 segments (Table 1). In addition, variable J\(\gamma\) usage patterns were seen in V\(\gamma\)1- and V\(\gamma\)3-containing transcripts for the three thymocyte waves. A high frequency of V\(\gamma\)1/J\(\gamma\)2 rearrangements in the first thymocyte wave was rearranged with the J\(\gamma\)1 segment in the first wave and with the J\(\gamma\)3 segment in the following waves.

A striking feature of the TCR-\(\gamma\) transcript analysis was the occurrence of recurrent clones exhibiting the same V\(\gamma\)-J\(\gamma\) junction in the second and third thymocyte waves (Fig. 7). (a) 30 identical V\(\gamma\)1-J\(\gamma\)1-C\(\gamma\) clones (2v12) were found in the second thymocyte wave and 9 such clones (3v14) were found in the third thymocyte wave. (b) 19 identical V\(\gamma\)3-J\(\gamma\)3-C\(\gamma\) clones were found in the second wave (2v32), and 7 clones of this type (3v32) were encountered in the third thymocyte wave. Thus, the low frequency of V\(\gamma\)1 and V\(\gamma\)3 subfamily usage in the second thymocyte wave was associated with an increased representation of repetitive clones.

**Figure 4.** Phenotypic analysis of recent thymocyte emigrants in the periphery. Thymocytes were randomly labeled by intrathymic injection of fluorescein. Blood samples obtained 12 h later were analyzed by immunofluorescence flow cytometry. Around 3-10% of the peripheral blood lymphocytes were FITC labeled. TCR-\(\gamma\)\(\delta\) or TCR-\(\alpha\)/\(\beta\) (V\(\beta\)1) were detected by phycoerythrin-coupled antibodies. Results are expressed in percent of fluorescein-labeled cells expressing either TCR-\(\gamma\)\(\delta\) and TCR-\(\alpha\)/\(\beta\) V\(\beta\)1 cells, and each point corresponds to the mean value for four recipients. Hatched areas indicate the peak periods of splenic and intestinal colonization by \(\gamma\)\(\delta\) and \(\alpha\)/\(\beta\)(V\(\beta\)1) T cells derived from the thymus (13, 21).

**Figure 5.** Ontogeny of TCR-\(\gamma\) transcripts. Identification of V\(\gamma\)1-J\(\gamma\)-C\(\gamma\), V\(\gamma\)2-J\(\gamma\)-C\(\gamma\), and V\(\gamma\)3-J\(\gamma\)-C\(\gamma\) transcripts by PCR amplification. Actin expression was used to standardize cDNA amounts and to allow semiquantitative analysis. Templates were cDNA from thymus at various stages of development. After 32 cycles of amplification, PCR products were electrophoresed, stained with ethidium bromide, and photographed. (A) Ontogeny of the different V\(\gamma\) transcripts in chicken embryos (B) Comparative analysis of the different V\(\gamma\) transcripts in the three developmental waves of thymocytes. Thymocytes derived from the first, second, and third wave of precursors were from E13 embryos, 1-d-old chicks (day 22), and 1-wk-old chicks (day 28), respectively. First, second, and third wave thymocytes were obtained from multiple embryos.

Differences in CDR 3 length were not observed in the repertoires generated by the three embryonic waves. However, an apparent increase in N/P nucleotide insertions at the V\(\gamma\)-J\(\gamma\) junction suggested an increase in CDR 3 diversity in the third thymocyte wave (Table 2).

**Figure 6.** TCR V\(\gamma\) segments observed in the H.B19ov\(^+\) chicken strain. Comparison of CooH-terminal amino acid sequences of the V\(\gamma\)1, V\(\gamma\)2, and V\(\gamma\)3 subfamily members identified for the H.B19ov\(^+\) chicken strain by sequence analysis of PCR-derived cDNAs. Residues identical to the prototypic sequence are represented by dashes. V\(\gamma\)1 segments are numbered according to Six et al. (16). V\(\gamma\)1-1 and V\(\gamma\)3-1 segment references were not encountered in our study; = new V\(\gamma\) members. Some members differ by several nucleotides, but code for the same amino acid sequence. The V\(\gamma\)2b2 member presents a stop codon (*) and might correspond to a pseudogene.
and J distinguish different thymocyte waves suggests that they differ in Vg usage as well as in CDR3 diversity. T cell repertoire differences also appear in mammals (35, 36), but can be examined in greater detail in the chicken because of embryonic chick thymus to generate three successive waves of T cell progeny members which leave the thymus to colonize peripheral organs such as the spleen and the intestine. The present studies indicate that each wave of progenitors gives rise first to \( \gamma/\delta \) thymocytes and then \( \alpha/\beta \) (V\( \beta1 \)) thymocytes 3 or 4 d later so that the \( \gamma/\delta \) and \( \alpha/\beta \) (V\( \beta1 \)) T cells migrate asynchronously from the thymus. Progenitor colonization of the thymus in waves and an accelerated rate of \( \gamma/\delta \) T cell differentiation thus contribute to the alternating emigration of first \( \gamma/\delta \) and then \( \alpha/\beta \) T cells to the periphery (Fig. 8). Analysis of the TCR-\( \gamma \) repertoire for the different thymocyte waves suggests that they differ in V\( \gamma \) and \( \gamma/J \) usage as well as in CDR3 diversity.

Thymus colonization by waves of hemopoietic progenitors also appears to occur in mammals (35, 36), but can be examined in greater detail in the chicken because of embryonic chick accessibility and the opportunity to purify the progeny of individual waves of progenitors. Adoptive transfer of alloantigen-marked progenitors allowed us to elucidate the homing routes whereby these enter the embryonic thymus. This analysis indicates that progenitors of bone marrow origin enter the thymus either via interlobular venules or capillaries located at the corticomedullary junction. Both routes have been described in the mouse, but were not shown to be used simultaneously, the transcapsule route thought to be restricted to thymus colonization before its vascularization (37, 38). In the congenic chick chimeras, progenitors entering at the corticomedullary junction subsequently migrated to the outer cortex of the thymus, where precursors entering through the capsule were also found. This outer cortical homing pattern of thymocyte precursors has also been noted after direct needle injection in mice. As has been described in mammals (37), thymocytes then migrate from the outer cortex as they undergo T cell differentiation en route to the thymic medulla.

An interesting question concerns whether each embryonic wave of precursors generates the same or different T cell repertoires. Studies of the TCR-\( \gamma \) repertoire generated during mouse development indicate sequential usage of V\( \gamma \) genes. The first \( \gamma/\delta \) T cells generated during embryonic development express V\( \gamma5-C-\gamma1 \) transcripts, the second population of \( \gamma/\delta \) T cells express V\( \gamma6-C-\gamma1 \) transcripts, and \( \gamma/\delta \) T cells become more heterogeneous for V\( \gamma \) usage after birth (22, 25). In similar fashion, the V\( \beta1 \) gene segments are rearranged before the V\( \beta2 \) gene segments during avian ontogeny (39). However, the V\( \gamma \) gene families do not undergo sequential rearrangement during ontogeny. The chicken TCR-\( \gamma \) locus consists of 3 V\( \gamma \) families with \( \sim10 \) members each, 3 J\( \gamma \) segments, and 1 C\( \gamma \) segments (15, 16). The first wave of thymocyte progeny rearrange all three V\( \gamma \) families and J\( \gamma \) genes as early as E10-E11. This type of unrestricted TCR-\( \gamma \) rearrangement pattern has also been suggested in sheep and humans (40, 41). On the other hand, preferential V\( \gamma \) J\( \gamma \) pairings were observed for the three developmental waves of thymocytes, whereas preferred TCR V\( \beta1/D/J \beta \) rearrangements were not apparent during ontogeny (13). The V\( \gamma \) J\( \gamma \) junctional variations (CDR3) for all three embryonic thymocyte waves were more limited than in the adult (16). Such differences between embryonic and adult repertoires have also been found in mammals (42). Finally, the nonproductively rearranged TCR-\( \gamma \) transcripts observed in TCR-\( \gamma/\delta-\gamma \) thymocytes indicate that V\( \gamma \) J\( \gamma \) rearrangements occur on both alleles in avian \( \gamma/\delta \) T cells.

A high frequency of repetitive TCR-\( \gamma \) transcripts was found in the second and third waves of thymocyte progeny, particularly in the second wave of thymocytes where two clones, 2v12 and 2v32, represented 97 and 66% of the V\( \gamma1 \) and V\( \gamma3 \) repertoires, respectively. This result could provide evidence for a selection process that favors certain V\( \gamma \) and J\( \gamma \) pairings. It is also possible that these repetitive transcripts reflect a high degree of homogeneity within each wave of thymocyte progenitors, as observed in other systems (43). Further studies are needed to clarify the factors that influence these patterns of TCR-\( \gamma \) repertoire diversity during thymus development.
represent a PCR artefact or a sampling error due to the limited numbers of cells being analyzed. However, several observations suggest that the TCR-γ repertoire may differ for the different waves. (a) The Vγ1 and Vγ3 repertoire diversities were higher in the third wave than in second, even though the number of g/d1 donor-derived thymocytes examined in the second wave was ten times higher than for the third wave (14×10³ versus 1.4×10³ g/d cells). (b) Reputitious clones were also encountered in the third wave repertoire, albeit at lower frequencies (31% for 2v12-3v14, 23% for 2v32-3v32). (c) The cDNA synthesis, PCR amplification, and product cloning procedures were repeated three times to confirm the findings. (d) Repetitive transcripts were not encountered in the Vγ2 repertoire preferentially used by the second thymocyte wave. Thus, the high frequency of repetitive invariant clones in Vγ1 and Vγ3 repertoires created by cells of the second wave is in agreement with a lower usage of Vγ1 and Vγ3 families in this wave.

Differences in the TCR-γ repertoire generated in each progenitor wave could reflect differences in the colonizing progenitors. The first wave of thymocyte progenitor are derived from multipotent hematopoietic stem cells that arose in the paraaortic region of the embryo (3), whereas the second and third wave of thymocyte progenitors were derived from the bone marrow. The generation of different TCR-γ repertoires could therefore reflect differences in the progenitor cells themselves. The differentiation kinetics of g/d and a/b (Vβ1) thymocytes were conserved for the three developmental waves of thymocyte progenitors. The times required for differentiation of γδ and α/β (Vβ1) thymocytes were ~9 and 12 d, respectively, in the chicken.
The accelerated differentiation of avian γδ versus α/β thymocytes has also been noted for mouse thymocyte precursors (43, 44). Different selection processes for the α/β and the γδ thymocytes may contribute to the differences in differentiation kinetics (45, 46). Different growth requirements during γδ and α/β T cell differentiation, such as IL-7 requirement, may also promote different differentiation kinetics (47).

The thymocyte emigration model whereby peripheral tissues are colonized by γδ T cells before α/β (Vβ1+) T cells may favor harmonious development of a strategic immune defense system mediated by interacting lymphocyte subpopulations. The interaction of γδ T cells with cells in the peripheral organs could provoke microenvironmental modification that favors the homing of α/β T cells. The location of γδ and α/β T cells in peripheral tissues may play an important role in the establishment of an immune response, in that recent evidence suggests γδ T cells may function as regulatory cells for α/β T cells (48–50). During organogenesis, new niches for lymphocyte homing may appear throughout development. The interspersed emigration of γδ and Vβ1 thymocytes might provide a mechanism to fill these niches by γδ and α/β cells in developing organs. The observed interspersed emigration of γδ and α/β (Vβ1+) thymocytes could also affect the homing patterns of specific thymocyte subpopulations. For example, two thymocyte subpopulations are emigrating from the thymus at day 21–23, the γδ thymocytes generated by the second wave of precursors and the minor second subpopulation of α/β (Vβ2+) T cells generated by the first wave of progenitors (8). Interestingly, γδ thymocytes colonize the intestine in massive numbers, whereas Vβ2 thymocytes are rarely seen in that organ (20). These two populations may compete for homing sites, thus diverting the Vβ2 population to other organs. Since an optimal immune response may require collaboration between γδ and α/β T cells, sequential migration of γδ and α/β thymocyte subpopulations may provide an efficient means to maintain a physiological balance between the two cell populations during development.
The authors thank Mark Dessing, Victor Hæder, Barbara Ecabert, and Birgit Kugelberg for excellent technical assistance; Jean Desrosiers, Hans Spalinger, and Beatrice Pfeiffer for photography; and Drs. Klaus Karjalainen, Hans Rember Rodewald, and Charley Steinberg for critical reading and improvement of the manuscript.
