Pediatric and Adolescent Extracranial Germ Cell Tumors: The Road to Collaboration

ABSTRACT

During the past 35 years, survival rates for children with extracranial malignant germ cell tumors (GCTs) have increased significantly. Success has been achieved primarily through the application of platinum-based chemotherapy regimens; however, clinical challenges in GCTs remain. Excellent outcomes are not distributed uniformly across the heterogeneous distribution of age, histologic features, and primary tumor site. Despite good outcomes overall, the likelihood of a cure for certain sites and histologic conditions is less than 50%. In addition, there are considerable long-term treatment-related effects for survivors. Even modest cisplatin dosing can cause significant long-term morbidities. A particular challenge in designing new therapies for GCT is that a variety of specialists use different risk stratifications, staging systems, and treatment approaches for three distinct age groups (childhood, adolescence, and young adulthood). Traditionally, pediatric cancer patients younger than 15 years have been treated by pediatric oncologists in collaboration with their surgical specialty colleagues. Adolescents and young adults with GCTs often are treated by medical oncologists, urologists, or gynecologic oncologists. The therapeutic dilemma for all is how to best define disease risk so that therapy and toxicity can be appropriately reduced for some patients and intensified for others. Further clinical and biologic insights can only be achieved through collaborations that do not set limitations by age, sex, and primary tumor site. Therefore, international collaborations, spanning different cooperative groups and disciplines, have been developed to address these challenges.

INTRODUCTION

Extracranial germ cell tumors (GCTs) are categorized as rare pediatric tumors. In children younger than 15 years, they account for approximately 3% of cancers. However, in adolescents (aged 15 to 19 years), this proportion increases to 14%.1,2 The successful introduction of cisplatin-based chemotherapy in adults with GCT from the 1970s informed the design of subsequent pediatric protocols.3-6

EARLY CLINICAL TRIALS IN PEDIATRIC GCTS

GCTs are a heterogeneous group with respect to patient age, histologic features, and primary tumor location. Pediatric clinical trial design, which has traditionally incorporated all extracranial GCTs, not just a particular extracranial site such as testicular, has been challenged by this heterogeneity, in conjunction with the rarity of the tumor itself. In most countries, prospective pediatric clinical trials were limited to patients younger than 15 years. Each international pediatric GCT clinical trial organization has developed its own risk stratification and treatment protocols (usually featuring nonrandomized, single-arm studies) for patients they would categorize as low, intermediate, or high risk. This is especially true with the staging of testicular GCTs, which will be discussed later.7,8 Age

HDPEb did not improve overall survival (OS), most likely because of
ular malignant GCTs (Table 2). For INT-0106, immature teratomas and stage I testic-
per day administered for 5 days) and etoposide (100 mg/m2 per day
uffles of serum tumor markers to normalize

ces regarding fatal pulmonary fibrosis.14,16 Pediatric BEP (PEb)
consistent of four cycles of standard adult doses of cisplatin (20 mg/m2
per day administered for 5 days) and etoposide (100 mg/m2 per day
administered for 5 days), with bleomycin (15 mg/m2) administered
only on day 1 of each cycle, rather than once per week as in adult
protocols. The overall 6-year survival rate for patients treated with PEb
was 95.7%.9

High-risk tumors, defined as stage III/IV ovarian, stage III/IV
testicular, and stage I-IV extragonadal malignant GCTs (all < 21 years)
were treated in Intergroup Study INT-0097. High-dose cisplatin (200
mg/m2) had shown promise both in a small randomly assigned trial
from the National Cancer Institute in poor-prognosis GCTs17 and in
the treatment of progressive neuroblastoma.18 Patients were ran-
omly assigned between high-dose (HDPEb) and standard-dose
(Peb) regimens.10 Despite improved event-free survival (EFS),
HDPEb did not improve overall survival (OS), most likely because of
increased therapy-related toxicity. The study was not powered to
detect differences in EFS or OS in separate strata. In addition, signifi-
cant ototoxicity was noted with high-dose cisplatin, which was
deemed unacceptable, especially given the young age of many patients
with extragonadal disease.10

eligibility varied, but these pediatric trials did include patients from the
adolescent young adult (AYA) cohort, although the numbers were small (Table 2). For INT-0106, immature teratomas and stage I testicu-
lar malignant GCTs (< 10 years) were managed with observation
only after initial surgery. Other tumors deemed low risk (INT-0106)
that required chemotherapy, defined as stage II testicular (< 10 years)
and stage I/II ovarian (< 21 years) malignant GCTs, were treated with
a modification of the successful adult bleomycin, etoposide, and cis-
platin (BEP) regimen, with reduced-dose bleomycin because of con-
cerns regarding fatal pulmonary fibrosis.14,16 Pediatric BEP (PEb)
2). Since 1989, because of toxicity concerns, the United Kingdom
historically been different from the United States’ approach. The first
approach by pediatric oncologists in the United Kingdom has
historically been different from the United States’ approach. The first
pediatric germ cell study used various chemotherapy regimens (Table
2). Since 1989, because of toxicity concerns, the United Kingdom
replaced cisplatin with carboplatin in its clinical regimens. Although
carboplatin had already been shown to be definitively inferior to
cisplatin in clinical trials in adults with testicular GCT,20,21 the higher
doses of carboplatin used in pediatric compared with adult trials
produced promising results in children.15 In the second GCT study,

Abbreviations: AFP, α-fetoprotein; BEP, similar to PEb but cisplatin given on day 1 and etoposide days 1-3; BLEO, bleomycin; CDDP, cisplatin; D, day chemotherapy administered; EFS, event-free survival; EG, ETOP, etoposide; GCT, germ cell tumor; HDPEb, PEb with high-dose cisplatin; INT, intergroup study; J, carboplatin; NA, analysis not available or published; OS, overall survival; PEb, pediatric BEP (four cycles of standard adult doses of cisplatin [20 mg/m² per day administered for 5 days] and etoposide [100 mg/m² per day administered for 5 days], but bleomycin [15 mg/m²] was administered only on day 1 of each cycle, rather than once per week); PR, partial response by markers or residual tumor; SCT, malignant sacrococcygeal teratoma.

*Median age and range were not always available.
137 patients (< 15 years) were treated with JEb (carboplatin [600 mg/m^2, equivalent to area under the [concentration-time] curve of 7.9 mg/mL per minute], etoposide [120 mg/m^2 administered for 3 days], and bleomycin [15 mg/m^2 on day 1 of each cycle]). Patients were treated with an n + 2' strategy, where patients were administered two further JEb cycles after documentation of radiologic and marker remission. The 5-year EFS and OS were 87.6% and 90.9%, respectively.15 The UK Children’s Cancer and Leukemia Group (CCLG) third study is now closed and awaiting analysis. In this trial, all standard-risk patients received four cycles, and high-risk patients received six cycles, of JEb. In the third study, therapy was not extended for two more cycles after remission was documented, to avoid potential overtreatment.

INTERNATIONAL PEDIATRIC GCT COLLABORATION

Every national pediatric GCT group has struggled with few patients and the stratifications.15,19,22,23 The lack of consensus between different national groups on the relative importance of age, site, stage, and elevation in tumor marker levels resulted in variable treatment approaches. National nonrandomized trials for pediatric GCTs from the French, German, and Brazilian germ cell groups are shown in Table 3. The major aspects of these trials were an attempt to modify therapy on the basis of response and, in German Maligne Keimzelltumoren studies, to use neoadjuvant chemotherapy before definitive surgery.24-27 Investigations also include the addition of ifosfamide and the deletion of bleomycin. Results were good, but there were no comparison groups and the number of patients was small.

There was consensus, however, for the need for further clinical innovation, with three key questions to be addressed: Could late effects be reduced through either the elimination of chemotherapy in patients likely to be cured by surgery or the substitution of cisplatin with similarly effective, but less toxic, drugs? Could clinical outcomes be improved in those patients who were unlikely to be cured with standard therapy? And could biologic markers of prognostic significance be identified? A major limitation to this task was that without a common language, such as the International Germ Cell Consensus Classification (IGCCC),28 developed for metastatic adult testicular GCT, designing trials across cooperative group boundaries would be impossible.

Consequently, investigators from the COG and CCLG established the Malignant Germ Cell International Collaborative (MaGIC) initiative and, in 2009, a memorandum of agreement was signed. Data from seven COG and CCLG pediatric GCT trials, which ran from 1985 to 2009 (Table 2), were combined to form a data set of more than 1,000 patients. The primary goals of the collaboration were to establish risk factors for disease recurrence, incorporate these into a common risk stratification, and use this stratification as the basis for subsequent clinical trials.

By using the parametric cure model29 to predict estimated long-term disease-free (LTDF) survival, multivariable analysis of the MaGIC data resulted in a revised risk stratification that was internally validated using the bootstrapping method (Table 4).30 Poor outcome was associated with patients age 11 years or older, tumor site (ovarian or extragonadal \( v \) testicular), and stage IV disease. Poor risk was defined as less than 70% LTDF survival. In this data set, neither elevation of tumor marker serum \( \alpha \)-fetoprotein (AFP) nor type of therapy (PEb \( v \) JEb) was predictive of outcome. The fundamental change in this risk-stratification system was the recognition that only children age 11 years or older were poor risk (expected LTDF survival, < 70%); younger children, even with advanced disease or extragonadal primary site, still had an excellent prognosis. The MaGIC database was an important first step toward development of treatment strategies on the basis of specified outcomes combining the importance of age, site, stage, and sex. However, although derived from the largest data set described in pediatric GCT, the parametric cure model warrants external validation in an independent cohort, which is currently being conducted using data from the Brazilian GCT-99 cohort.27

The MaGIC pediatric data set is limited by relatively few adolescents (11 to 15 years) and even fewer adolescents older than 15 years and young adults. However, in a single-institution case series, adolescents with testicular GCT, controlling for IGCCC risk group, stage, and histologic features, had a lower 3-year EFS (59.9%) compared with children (87.2%) or adults (80.0%). This GCT study replicates the inferior outcomes for AYA in other malignancies. The cause of this survival gap is likely multifactorial: adolescent patients may experience fragmented care, under-representation in clinical trials, and, perhaps, a contribution from inherently more aggressive biologic factors.31-33 Consequently, to further examine how the outcomes in adolescents compare with outcomes in adults, the MaGIC consortium has been expanded to include cohorts of AYA with GCT treated by other cooperative groups. Ovarian and testicular AYA data sets have been provided by the Gynecologic Oncology Group (GOG) and the UK Medical Research Council. The outcomes of adolescent versus young or older patients were analyzed with the goal of validating (and if necessary, amending) the MaGIC revised risk classification,30 thus generating a final common language for future clinical trials.

One large obstacle to comparing outcomes of treatment for adolescents with GCT is the fact that each cooperative group has evolved its own staging system, which may or may not be comparable. Substantial differences exist between the COG pediatric staging system, the American Joint Committee on Cancer (AJCC) testicular staging system (Appendix Table A1, online only), the IGCCC metastatic testicular system (Table 5), and the International Federation of Gynecology and Obstetrics (FIGO) staging system used for ovarian GCT (Appendix Table A2, online only).7,8 Staging of adult testicular GCT may be rationally divided into stage I and advanced/metastatic (outside the testis) disease. Stage I is consistent across age groups. Pediatric stages II to IV testicular GCT would be considered advanced/metastatic disease and be classified in various subcategories (stages II and III) in the AJCC system. The discussion of these differences between the pediatric and adult testicular classifications becomes important when comparing studies in adolescents. Data on adolescents with either staging system are limited. Unfortunately, pediatric data sets lack the important information necessary for AJCC staging. In clinical practice, IGCCC risk-based staging may be more important for determining actual treatment. The FIGO system has been developed for all ovarian cancers, most of which are epithelial (Appendix Table A2). The FIGO management of such tumors dictates substantially more abdominal and pelvic lymph

NOTE. Secreting GCT refers to elevated tumor markers, usually α-fetoprotein. Abbreviations: A, actinomycin; B, bleomycin; BEP, bleomycin, etoposide, and cisplatin; CI, continuous infusion; COG, Children’s Oncology Group; CR, complete remission; D, day chemotherapy administered; E, etoposide; EFS, event-free survival; EG, extragonadal; FIGO, International Federation of Gynecology and Obstetrics; GCT, germ cell tumor; GCT-91, Brazilian pediatric GCT trial; HPE, higher than standard cisplatin and etoposide; HR, high risk; I, ifosfamide; IR, intermediate risk; J, carboplatin; MAKEI, German pediatric GCT trials; OS, overall survival; P, cisplatin; PE, cisplatin and etoposide; PEI, cisplatin, etoposide, and ifosfamide; PVB, cisplatin, vinblastine and bleomycin; TGM, French pediatric GCT trials; V, vinblastine; VIP, vinblastine, ifosfamide, and cisplatin.
node sampling than historically has been performed for ovarian GCT. The FIGO system has both similarities and differences compared with pediatric GCT staging. One example is peritoneal leakage of tumor, which would be defined as stage III disease using pediatric staging, but only stage IC using FIGO; however, on the basis of age, both cohorts of patients would receive similar therapy. Pediatric stage I would be comparable to FIGO stage IA/IIB, and patients in this group might be candidates for identical treatment. It is clear that adult staging systems contain more subdivisions than does COG pediatric staging. The staging systems may be comparable if all relevant clinicopathologic data required to make such assignments are made available. A prospective trial that collects all such data may be able to answer this question.

**COLLABORATION AND FUTURE APPROACHES**

Despite the constraints of different staging systems and risk assignment, US and UK pediatric groups are now exploring opportunities for collaboration in future clinical trials with both adult and other pediatric study groups, building on the success of the MaGIC collaboration. In this setting, the next set of GCT clinical trials might be jointly sponsored by pediatric and adult clinical trial organizations. A trial for low- and intermediate-risk GCTs is currently under development. This trial will be cosponsored by COG and the newly formed US National Research Group, which includes GOG. Patients from birth to age 50 years will be eligible. According to the COG staging system (Table 1), low-risk patients are defined as any stage I patient, including testicular, ovarian, and extragonadal sites. Recommended therapy will be active surveillance, which is an accepted strategy for pediatric and adult patients with testicular cancer. However, active surveillance will now be extended to all adult women with FIGO stage IA/B ovarian GCT (Appendix Table A2), after comprehensive staging according to GOG guidelines, and all patients with COG stage I extragonadal GCT (Table 1), who would currently receive chemotherapy as standard care. In reality, most patients with localized stage I extragonadal GCTs are young pediatric patients with sarcomatoid or germ-cell malignancy; thus, this protocol will be a significant change in clinical practice for adult women with ovarian tumors and children with stage I extragonadal GCT. In addition, this trial will allow a critical reassessment of current COG and GOG ovarian staging guidelines.

For intermediate-risk patients, the protocol will be a randomly assigned comparison of regimens containing carboplatin versus cisplatin (Fig 1). Eligibility will include all patients, except those with stage I testicular and extragonadal disease, those with FIGO stage IA/B ovarian tumors, and patients defined as having a poor prognosis (patients > 11 years with either stage IV ovarian or stage III/IV extragonadal GCT, and patients > 15 years with IGCCC intermediate- or poor-prognosis testicular GCT). In the MaGIC analysis, outcomes with carboplatin using PBp were not significantly different than outcomes with JEp, either overall or in any individual risk group. This trial will test PBp versus JEp (area under the [concentration-time] curve of 7.9 mg/mL per minute) in children younger than 11 years and the adult regimen of BAp versus the regimen of carboplatin, etoposide, and bleomycin (administered once per week) in

NOTE. Adapted from the International Germ Cell Cancer Collaborative Group. The International Germ Cell Consensus Classification is a prognostic factor–based staging system for metastatic germ cell cancers.

Abbreviations: AFP, a-fetoprotein; HCG, human chorionic gonadotropin; LDH, lactate dehydrogenase; RP, retroperitoneal; S0, normal marker; STM, serum tumor marker; S1, S2, S3, range listed above; ULN, upper limit of normal.

*Nonpulmonary visceral metastasis refers to metastasis involving organs other than lung (lymph nodes do not count).
AYA patients age 11 to 25 years (Fig 1). The number of courses of chemotherapy delivered within and between each arm will be determined by analyses of the completed COG AGCT0132 study, which are in progress.

Because outcomes in children with GCT younger than 11 years are excellent, the pediatric collaboration on this trial will be extended beyond COG and CCLG, to have sufficient power to investigate whether carboplatin is comparable to cisplatin in terms of EFS. Three large pediatric clinical centers will therefore be included: Boldrini Children’s Cancer Hospital (Campinas, Brazil), TATA Memorial Hospital (Mumbai, India), and Children’s Cancer Hospital (Cairo, Egypt). These three centers have appropriate approvals for participation in international pediatric clinical trials.

Through the application of the IGCCC staging system, men with metastatic GCT can be assigned to good-, intermediate-, and poor-prognosis categories (Table 5). The term stage IV testicular GCT has subsequently been expanded and analyzed in the MaGIC data set and adult germ cell studies. The MaGIC data set will be expanded and analyzed in addition, all studies will emphasize coordination of the collection of tumor material for biologic studies. BEj, carboplatin, etoposide, and bleomycin (administered once per week); BEp, cisplatin, etoposide, and bleomycin (administered once per week); CCLG, Children’s Cancer and Leukemia and Cancer Group; COG, Children’s Oncology Group; GOG, Gynecologic Oncology Group; IGCCC, International Germ Cell Consensus Classification; JEb, carboplatin, etoposide, and bleomycin (administered once per week); TIGER, Randomized Phase III Trial of Initial Salvage Chemotherapy for Patients with Germ Cell Tumors. A potential collaborative strategies

Risk classification was applied to all such adolescent males with metastatic testicular GCT, a group with less than 80% LTDF survival. Even when the IGCCC risk classification was applied to all such adolescent males with metastatic testicular GCT, a group with less than 80% LTDF survival could not be identified. This may be because most patients in the IGCCC analysis, postpubertal males (≥ 11 years) with testicular stage II/III extragonadal stage II testicular stage III/IV with IGCCC good risk) and testing multiple strategies simultaneously can be extended (or other regimen).
etoposide, administered every 2 weeks (instead of every 3 weeks), with bleomycin administered once per week and growth factor support. Although the cycles with cisplatin and etoposide were compressed, patients still received all 12 bleomycin doses, administered once per week. The phase I/II data showed favorable toxicity and promising efficacy.53

Another approach for patients with poor-risk GCT is whether those patients who are likely to experience failure of standard BEP treatment can be identified early during BEP treatment and switched to more intensive therapy in real time. Retrospective reports have suggested that men with GCT and inadequate tumor marker decline (AFP) after initiation of chemotherapy are a poor-prognostic group.50,54 A recent randomized trial, GETUG 13,55 intensified therapy among patients with a poor AFP marker response to one cycle of BEP. There was a 10% increase in EFS compared with those who continued to receive standard-dose BEP; however, OS was similar between the two groups. The complexity of the GETUG 13 regimen, as well as the inclusion of insufficiently active or more toxic therapy, makes widespread adoption of this strategy unlikely. However, continued investigations of potential response-based strategies should be pursued.

Collaborators in pediatric oncology, medical oncology, and gynecologic oncology have discussed proposals for patients age 11 years and older with poor-risk disease. The premise was that an RCT with increased sample size, including male and female AYA with the same predicted poor outcome, was feasible. Perhaps, planning of a tentative joint RCT, simultaneously evaluating two or, perhaps, three of the most promising strategies (Fig 1), was possible. Several promising regimens, such as Accel-BEP,53 carboplatin, bleomycin, vincristine, and cisplatin with BEP (CBOP-BEP),56 and first-line paclitaxel, ifosfamide, and cisplatin (TIP),56 are being discussed. In the interim, pediatric groups continue to explore opportunities for collaboration with adult cooperative trial groups to establish feasibility of this strategy as a means to increase accrual and expedite evaluation of new approaches, especially in AYA. One option might be joining a currently open poor-prognosis adult GCT trial. One regimen under consideration for a multiarm trial is the currently active study, ANZUP 1302 (Australia and New Zealand), a phase III RCT of standard BEP versus accelerated BEP treatment for patients with IGCCCG intermediate- and poor-prognosis GCT. This approach might provide the opportunity to demonstrate that a pediatric clinical trial group and a testicular cancer trial group can collaborate successfully across international boundaries.

Fortunately, for patients with relapsed GCT, salvage therapy is often successful. Salvage therapies have included other conventional chemotherapy agents, such as the TIP regimen and high-dose chemotherapy with or without stem-cell rescue.50,57-61 However, the lack of RCTs in patients with relapsed GCT has not allowed for identification of the optimal salvage therapy. An international collaborative RCT, the Randomized Phase III Trial of Initial Salvage Chemotherapy for Patients with Germ Cell Tumors (TIGER) study (Alliance 0311102/EORTC 1407), will compare OS in patients with relapsed GCT treated with TIP or paclitaxel and ifosfamide, followed by high-dose carboplatin/etoposide. More important, because of the previous engagement of the pediatric and adult testicular communities through MaGIC, COG has been invited to cosponsor the Alliance trial, and the concept has been approved by the COG Science Council. The TIGER trial is expected to open in 2015.

**CONCLUSION**

For too long, the study of GCT has been hampered by arbitrary clinical divides on the basis of age and sex. We can enhance the study of GCT through the generation of large clinical trial data sets that encompass all age groups and multiple cooperative groups with different treatment strategies. The planning of joint future trials is moving forward because of the persistent efforts of many groups. These studies will include an international attempt to prospectively collect biologic specimens that may ultimately improve diagnosis, disease monitoring, and risk stratification, and identify potential targets for treatment. Well-designed RCTs should allow improvement of clinical outcomes with reduced toxicity. One more facet about the study of rare pediatric cancers should be noted: Funding limitations have particularly hampered the study of GCT. The MaGIC studies and present collaborations could not have occurred without strong support and funding from COG and CCLG, as well as the Teenage Cancer Trust (United Kingdom) and other charities, such as the Katie Walker Fund (United Kingdom), Bridging the GAP (United States), The Franklin Foundation (Unites States), and the Dana Farber/Boston Children’s Cancer and Blood Disorders Center. Investigators and patients are indebted to these valiant people.

**BIOLOGICALLY-BASED TREATMENT**

Advancement of biologic understanding of GCT, both pediatric and adult, is essential. Definitive pediatric GCT biologic studies have historically been hampered by the lack of available specimens, a hurdle that has been overcome by the MaGIC collaboration. Key differences in genomic changes have been identified in mediastinal tumors in children younger than 8 years and in those 8 years or older.62 The patterns of gains and losses were similar to age-matched GCTs at other sites. In studies of adults with GCT, a prognostic mRNA gene expression signature was identified and validated with relatively few patients with poor clinical outcome.63 However, Palmer et al64 showed that GCTs in children have a protein-coding gene expression profile distinct from GCTs occurring in adults; therefore, whether the adult prognostic mRNA signature applies to children and adolescents remains to be determined. Other biologic parameters (eg, microRNAs) seem to be universally clinically informative in GCTs.65,66 It is hoped that collaboration will enhance not only understanding of basic GCT biologic features in children, adolescents, and young adults, but may enhance diagnosis, disease monitoring, risk stratification, and the identification of targetable mutations across the diverse clinical spectrum of extracranial GCT disease.
