Abstract

Varying susceptibility during menstrual cycling could be a factor for S(H)IV infection risk in female rhesus macaques. We retrospectively determined vaginal SIV infection time points relative to the menstrual cycle in a group of rhesus macaques (n = 11) enrolled in an HIV transmission trial. Eight of nine rhesus macaques became infected around menstruation time.

Keywords

SIV; progesterone; rhesus macaque; menstrual cycle

Introduction

Experimental vaginal S(H)IV infection of rhesus macaques can be more unpredictable than of pigtail macaques [4, 7]. This has limited the use of the species for research on HIV interventions for women. One hypothesis is that susceptibility fluctuations within menstrual cycles and irregular cycles contribute to the unpredictability. To begin to address the issue we here estimated infection time points within the menstrual cycle of rhesus macaques after they had successfully been infected in a recently completed transmission study [1].

A repeat-low dose SIVmac251 virus exposure model was used, thus mimicking the human condition where not every HIV exposure leads to infection. The model was adapted from pigtail macaque models where we have previously summarized infection time points of 43...

SHIV-infected pigtails serving as controls in HIV prevention research studies [5, 13]. We also documented cycling in 3 additional pigtails that remained uninfected [5]. We reported that pigtail macaques have peak susceptibility to SHIV infection one week prior to and one week following menstruation [5]. This is likely due to hormonally-regulated fluctuations in immunity and the vaginal epithelium [14]. Unlike pigtails, however, wild rhesus macaque groups are seasonal breeders with mating and conceptions during the fall and winter, and births during the spring and summer, along with social hierarchies [3, 8]. Group members’ ovulation is reportedly variable, and only some group members give birth, and usually only in spring [3]. It is unclear how the processes play out in captivity, and whether they affect experimental SIV acquisition. In this pilot study, we retrospectively determined menstrual cycling in relationship with SIV transmission time point in 9 infected rhesus macaques, and in 2 macaques that remained uninfected after receiving six vaginal challenges [1].

Methods

Macaques

Twelve captive, cage-housed adult female Indian rhesus macaques (Macaca mulatta) of Indian origin served as mock IgG-treated controls during a study testing anti-a4b7 integrin treatment [1]. They were born and housed at the Yerkes National Primate Research Center (YNPRC) of Emory University (Atlanta, GA) [1]. Animals were maintained according to the guidelines of the Institute of Laboratory Animal Resources and with approval of Emory University’s IACUC [1, 9].

Virus Challenges, Hormone Analysis

Starting in February, rhesus macaques (n=12) were challenged intra-vaginally with a 1:20 dilution (5,000 TCID₅₀) of SIVmac251 in 1.0 ml of RPMI once weekly, resulting in infection of 10 animals after six or fewer challenges [1]. Challenges began in February and thus happened at the end of cycling season that reportedly lasts until the end of February. To determine the time point when nascent infection reached 50 copies/ml of plasma, viral loads were monitored by using bDNA quantitation on plasma aliquots [1]. Plasma was frozen at ~80°C and shipped to the University of Wisconsin National Primate Research Center for progesterone analysis [10, 13]. An infected animal with ID RCd12 [1] had no samples available for analysis. Only 11 of the 12 rhesus macaque plasma samples were available to measure progesterone levels. Rising plasma progesterone was considered evidence of ovulation. We defined cycle day one as the time point post-steepest progesterone decline as previously described [13]. This allowed us to determine the menstrual cycle time point when SIV infection was first detected at greater than 50 copies/ ml of plasma.

Results

Ten animals had progesterone peaks during a total of six virus exposures (Fig. 1), while one animal Rlq9 did not (Fig. 1E). All nine infected animals were cycling at time of infection. Their first positive viral load was recorded on menstrual cycle days 1, 6, 6, 8, 8, 12, 12, 14, and 27 (Fig. 2A). Two macaques remained uninfected (Fig. 1E, H); animal Rlq9 was not cycling, and cycling status of RTm11 was indeterminate. In Fig. 1, occasional measurements
during winter months preceding the virus challenges are shown to demonstrate that some
animals had progesterone peaks, although sampling was too infrequent for meaningful
menstrual cycle diagnosis (unconnected dots in Fig. 1). The time point of initial viremia in
the nine infected macaques was found to be in the follicular phase (cycle days 1–16) of 8
macaques (95%), as compared with in the luteal phase for only 1 macaque (cycle days 17 –
32, 5%; Fig. 2A). Accounting for an estimated eclipse phase of seven days between virus
transmission and first detected plasma viremia, all but one macaque became infected one
week prior to or one week following menstruation (Fig. 2B). Progesterone peaks were
delayed or stopped fluctuating in March and April for at least one month in all animals
except for RIq9 and RTm11 (Fig. 1E, H).

Discussion

We used samples of opportunity to study whether rhesus macaques have fluctuating
susceptibility to vaginal infection during menstrual cycling, as we have shown in pigtail
macaques. Similar to pigtail macaques, eight of nine infected rhesus macaques preferentially
became infected around menstruation time suggesting that rhesus macaques also are more
susceptible to SIV following times of high progesterone [3, 8, 14]. This also confirms results
by Sodora et al., who found increased virus acquisition in luteal phase when rhesus
macaques were exposed in follicular or luteal phase [12]. We were limited to samples from a
study in which 9 of 11 females became readily infected. It was not possible to study
comprehensively why many female rhesus macaques are reportedly resistant to vaginal
infection. All nine infected animals were cycling; it is possible that a lack of cycling in other
parts of the year mostly accounts for the resistance. Consistent with this, one of the two
resistant animals had no evidence of cycling (Fig. 1E), while our second resistant animal was
indeterminate at the time of virus exposure, and could not be sufficiently analyzed because
very few blood samples were available (Fig. 1H).

It is possible that other factors contribute to rhesus macaques’ resistance to infection. For
example, rhesus macaques have considerably thicker vaginal epithelium than pigtail
macaques, including greater levels of superficial vaginal keratinization throughout the
menstrual cycle, and less thinning during the luteal phase [2, 4, 11].

The exact eclipse phase in each macaque was not known, because it is impossible to
determine which of the repeated challenges caused infection. We therefore used seven days
for an estimated eclipse phase as in previous studies [6]. It would be beneficial to analyze
additional animals after year-round virus inoculations and cycle determinations in frequently
collected samples. This could further elucidate the relationship between menstrual cycles
and vaginal infection in captive rhesus macaques and further explore the usefulness of repeat
low dose mucosal virus exposure in female rhesus macaques.
