Abstract

Non-Hodgkin lymphoma (NHL) constitutes a collection of lymphoproliferative disorders with widely varying biologic, histologic and clinical features. For the B-cell NHLs, great progress has been made due to the addition of monoclonal antibodies and, more recently, other novel agents such as B-cell receptor signaling inhibitors, immunomodulatory agents, and proteasome inhibitors. Autologous hematopoietic cell transplantation (auto-HCT) offers the promise of cure or prolonged remission in some NHL patients. For some patients, however, auto-HCT may never be a viable option, while in others their disease may progress despite auto-HCT. In those settings, allogeneic HCT (allo-HCT) offers the potential for cure. Over the past 10–15 years, considerable progress has been made in the implementation of allo-HCT, such that this approach now is a highly effective therapy for patients up to (and even beyond) age 75. Recent advances in conventional lymphoma therapy, peri-transplant supportive care, patient selection, and donor selection (including the use of alternative hematopoietic cell donors), has allowed broader application of allo-HCT to NHL patients. As a result, an ever-increasing number of NHL patients over age 60–65 years stand to benefit from allo-HCT. In this review, we present data in support of the use of allo-
HCT for patients with diffuse large B-cell lymphoma, follicular lymphoma, and mantle cell lymphoma. These histologies account for a large majority of allo-HCT performed for patients over 60 in the U.S. Where possible, we highlight available data in older patients. This body of literature strongly supports the concept that allo-HCT should be offered to fit patients well beyond age 65 and, accordingly, that this treatment should therefore be covered by their insurance carriers.

INTRODUCTION

In many cases of high risk NHL, the only potentially curative option for patients (regardless of age) remains allo-HCT. With recent advances in pre-, peri-, and post- transplant care, allo-HCT can now successfully be applied to a wider group of patients, including those with advanced age. While it is true that advanced age does increase the risk of transplant-related complications and non-relapse mortality, allo-HCT still often represents the only realistic option for cure for many older patients. After careful consideration of risks, benefits, and alternatives to allo-HCT, an increasing number of patients into their 70s are electing to undergo allo-HCT.

We present separate sections in which we briefly review the features of three B-cell NHL subtypes: diffuse large B cell lymphoma (DLBCL), follicular lymphoma (FL), and mantle cell lymphoma (MCL). These three lymphoma histologies accounted for 73% of allo-HCT performed for patients over age 60 in the U.S. between 2010–2014. [1] In each section, we include a brief overview of the use of non-transplant frontline therapies. We next briefly review outcomes for auto-HCT, and then focus primarily on available data supporting the use of allo-HCT. We then discuss data specifically supporting allo-HCT in elderly lymphoma patients.

DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL)

Overview of DLBCL and non-transplant options for frontline therapy

DLBCL, the most common type of aggressive non-Hodgkin Lymphoma, encompasses several clinical-pathologic entities. While risk factors include HIV infection, solid organ transplantation, and auto-immune disorders, most cases are sporadic and occur predominantly in individuals age >60 years with no obvious predisposing factors. Overall, 60% of those affected will be cured with chemoimmunotherapy. Clinical factors such as the NCCN-International Prognostic Index (NCCN-IPI), however, delineate a wide range of results identifying groups with likelihood of 5-year survival as high as 96% and others as low as 38%. [2,3] A greater understanding of biology and genetics has refined prognostic markers with potential therapeutic implications, such as the putative cell of origin (defined by gene expression profile or immunohistochemistry),[4,5] and translocation or overexpression of the MYC oncogene. [6]

Despite these advances, several disease subsets represent high-risk disease, clinically defined by the NCCN-IPI [2], or biologically identified, for example the “double-hit” and “triple-hit” lymphomas (i.e. those with MYC, and BCL2 and/or BCL6 translocations). Particularly for double and triple hit lymphomas, standard frontline therapies are ineffective for
providing long-term remission, and cure is rarely achieved in the relapsed and refractory settings. Selecting the optimal therapy for such patients therefore remains a great challenge. [6,7]

**Auto-HCT for DLBCL**

High-dose chemotherapy with auto-HCT exploits the steep dose-response curve of some chemotherapy agents, by eradicating disease that could not be eliminated by conventional chemotherapy doses. Two decades ago, one randomized trial conducted in relapsed aggressive lymphomas patients with chemosensitive disease showed a 53% 5-year survival with auto-HCT vs. 32% with continuation of conventional chemotherapy. [8] Even in the rituximab era, some patients whose disease relapses will be long-term survivors after proper second-line therapy and auto-HCT. [9] However, for patients who never achieve CR with frontline therapy, who have a short duration of CR, or relapse with a high IPI, significantly worse results are expected. For example, in the CORAL trial, fewer than 25% of patients who relapsed within one year of diagnosis achieved long-term disease-free survival with auto-HCT. [10]

Investigations designed to improve upon auto-HCT such as modifying the transplant preparative regimen with the addition of radioimmunotherapy to the chemotherapy backbone [11], or use of post-transplant maintenance therapy have not proven beneficial in relapsed/refractory (R/R) DLBCL. [12] Auto-HCT remains the standard of care for chemosensitive R/R DLBCL, but for subjects who experience relapse after auto-HCT, or for whom auto-HCT is not an option because the NHL is not sufficiently chemosensitive, better approaches are needed.

**Allogeneic transplantation for DLBCL**

Recent studies of allo-HCT involving at least 40 DLBCL patients are shown in Table 1.

Allo-HCT provides the theoretical advantage of a tumor-free graft and the benefit of a graft-versus-lymphoma (GVL) effect. This GVL effect has been well demonstrated by the fact that some patients who experience relapse after auto-HCT will attain cure with allo-HCT. Further, use of donor lymphocyte infusion (DLI), withdrawal of immune suppression, or the combination provides a GVL effect in DLBCL after allo-HCT, leading to cure in some cases. [13–15] Allo-HCT, however, presents challenges including donor availability, the need for prolonged immunosuppression and an increased risk of early treatment-related mortality due to toxicity of conditioning regimen, graft-versus-host disease (GVHD), and infectious complications. Progress has been made in recent years in addressing these challenges.

In the past, allo-HCT utilized myeloablative (MA) conditioning in order to eliminate maximal tumor and permit engraftment by eliminating the host immune system. No prospective trials comparing auto-HCT versus MA allo-HCT for R/R DLBCL have been undertaken. A large retrospective analysis by the Center for International Blood and Marrow Transplant Research (CIBMTR) including 837 auto-HCT and 79 allo-HCT performed between 1995 and 2003 demonstrated higher treatment-related mortality (TRM)/non-relapse mortality (NRM), and higher overall mortality in the allo-HCT group with no decrease in
risk of disease progression. [16] Those subjects who underwent allo-HCT, however, were more likely to have high-risk disease features including higher disease stage, received more prior chemotherapy regimens, and had resistant disease.

Despite such limitations, when reviewing the literature in allo-HCT, there is a consistent message that long-term OS in the 20–50% range is possible (see Table 1). The 25–30% NRM rate remains the largest drawback. Implementation of a less intensive preparative regimen (termed reduced-intensity conditioning [RIC]) has been utilized in recent years. Retrospective comparisons between MA and RIC show reduction of NRM, at the expense of some increase in disease relapse, but producing long-term OS rates comparable to MA conditioning. [17,18] Most allo-HCT for DLBCL are now performed using lower intensity regimens, which also permits undertaking this procedure in older patients who otherwise were good transplant candidates but previously would have been excluded from MA transplants due to age. [17] The expanding use of allo-HCT in older patients is evident by the fact that the more recent studies on Table 1 include patients 65–72 years of age. One recent study focusing on the use of allo-HCT in NHL patients in their 60s and early 70s, found that there was not a major increase in NRM for such patients. [19]

**Allogeneic HCT for DLBCL patients following a failed auto-HCT**—Approximately 30–40% of DLBCL auto-HCT recipients ultimately will experience relapse or progression of DLBCL and cannot be cured with intensification of chemotherapy. As noted above, because of the GVL effect in DLBCL, such patients are often considered for allo-HCT after a failed prior auto-HCT. [20–23] These studies report TRM/NRM rates of 17–31% but OS rates at 3–5 years of 34–52%. In the most recent and largest study, from the CIBMTR, 503 patients were analyzed. At 3 years, NRM was 30%, with a progression/relapse rate of 38% and OS of 37%, a reasonable result given that the median survival typically seen in this population is in the 3–10 month range. [24,25] In multivariate analysis, advanced age was not a prognostic factor, indicating that chronologic age should not be the key factor used to determine allo-HCT eligibility. A prognostic model was constructed using KPS <80, time from auto-HCT to allo-HCT of < 1 year, and chemo-resistant disease as adverse factors. This model facilitates identification of high-risk patients unlikely to benefit from allo-HCT (3 year OS of 14%) as well as low risk patients who have a good potential to benefit from allo-HCT (3 year OS of 43%). [23]

**Summary – DLBCL**

These data indicate that medically appropriate DLBCL patients whose disease relapses after auto-HCT have the clearest indication for allo-HCT and potentially can be cured. In this setting, patients preferentially should receive RIC, ideally after debulking conventional therapy. Other subsets of patients who may benefit from allo-HCT are subjects known to have a low chance of cure with auto-HCT, as identified by use of the second-line IPI, failure to attain CR using initial therapy, relapse <12 months after chemoimmunotherapy, or NHL refractory to second and third-line chemotherapy. [10,13,18,26] The recently developed CIBMTR prognostic model described above can guide decision-making. [23] Other appropriate indications include: 1) patients in whom auto-HCT is not feasible, either by failure to obtain an adequate autologous graft for transplant, or coexistence of intrinsic bone...
marrow disease, particularly myelodysplastic syndrome; 2) DLBCL transformed from an indolent B-cell malignancy relapsing after anthracycline-containing therapy, or a failed auto-HCT; and 3) “double hit” DLBCL.

FOLLICULAR LYMPHOMA (FL)
Overview of FL and non-transplant options for frontline therapy
FL comprises the most common subtype of indolent NHL, accounting for roughly 20% of all cases of NHL. Unlike patients with aggressive NHL, nearly all subjects who complete induction therapy will relapse and require additional lines of therapy. Furthermore, while the OS for many patients is prolonged, with standard therapies FL remains incurable for the vast majority of patients. The follicular lymphoma international prognostic index (FLIPI) incorporates clinically-based features and identifies a subgroup at high risk for early disease-related death. [27] Approximately one quarter of all FL patients fall into this poor-risk category (i.e., ≥3 risk factors), and have an estimated 5-year OS of only 53%.

A proportion of patients may be observed safely without treatment until the development of symptomatic progressive disease, bulky adenopathy, cytopenias, organ obstruction, or malignant fluid collection. [28] Patients who require therapy, but who otherwise have low tumor burden, may be managed with single-agent rituximab. [29] The majority of patients, however, warrant combination chemoimmunotherapy. Currently, bendamustine-rituximab (B-R) may be a preferred front-line approach in high tumor burden FL with improved progression-free survival (PFS) (median not reached vs 41 months, p=0.0072) and decreased toxicity compared to R-CHOP. [30]

There is no standard therapy for R/R FL, and readily available options include anti-CD20 immunotherapies, combination chemotherapy, radioimmunotherapy, the oral PI3 kinase inhibitor idelalisib, immunomodulatory drugs (lenalidomide), and the Bruton’s tyrosine kinase (BTK) inhibitor ibrutinib. [31] More intensive treatments often are considered for high-risk patients, especially those who relapse early after induction therapy, since relapse within 2 years of initial therapy is associated with a 5-year OS of only 50%. [32] In this context, auto-HCT and allo-HCT can provide for long-term survival in R/R FL.

Auto-HCT for FL

Auto-HCT for FL in first remission—The data to support autologous HCT for FL in first remission are limited. Prospective randomized trials comparing chemotherapy with auto-HCT in first complete remission have generally shown a PFS benefit but not OS benefit in favor of up-front auto-HCT. [33–36] Benefit in terms of improved lymphoma-specific survival appears to be offset by a decrease in survival due to secondary malignancies such as myelodysplastic syndrome and acute myeloid leukemia. As a result, auto-HCT is not recommended for consolidation of remission after first-line therapy for low grade FL.

Auto-HCT for R/R FL—While auto-HCT can produce prolonged remissions, it typically is not viewed as curative therapy in R/R FL. Prospective studies are lacking, although one randomized study (N=89) from the pre-rituximab era, closed early due to poor accrual, showed improved 2-year PFS and 4-year OS improved in auto-HCT recipients compared to
standard chemotherapy patients [37] A review of two French studies, which included patients who did and did not receive rituximab at the time of relapse, demonstrated that rituximab appeared to have a more prominent impact on event-free survival (EFS) and OS than did receipt of an auto-HCT. [38] At least nine additional single-center retrospective studies and large registry studies of R/R FL have demonstrated PFS in the 30–60% range at 5–10 years, although not all patients in these series were treated with rituximab. [39] Since a large majority of FL patients relapse after auto-HCT, this approach cannot be considered a curative intervention for most FL patients.

**Allo-HCT for FL**

There are no randomized prospective trials or retrospective studies to support the application of allo-HCT as consolidation for FL in first remission. However, there have been numerous prospective as well as retrospective studies that support the use of allo-HCT in R/R FL. Outcomes for selected studies investigating allo-HCT in R/R FL are presented in Table 2.

**Allo-HCT for R/R FL: Prospective Studies**—Shea et al [40] reported on a prospective study of 16 patients receiving RIC allo-HCT conditioned with fludarabine/cyclophosphamide and a matched related donor graft. The 3-year EFS was 75% and 3-year OS was 81%; 3 subjects relapsed. A second prospective study of 47 patients conducted at MD Anderson Cancer Center used RIC conditioning (fludarabine, cyclophosphamide, and rituximab conditioning). [41] The median 5 year PFS and OS were 85%; seven patients died, mostly from infectious complications. Another report combined two, prospective multi-center Spanish trials in 37 patients given a fludarabine/melphalan RIC regimen. [42] The relapse incidence was only 8%, but NRM was as high as 71% for patients with active disease prior to allo-HCT. For patients in CR prior to transplant, the 4-year OS was 71%, comparable to other studies. A prospective study from the U.K. enrolled 82 consecutive FL patients treated with fludarabine, melphalan and alemtuzumab and RIC. NRM was 15% and only 26% of patients experienced a relapse at 4 years, and OS was 76% at 4 years. [43] Finally, another prospective multi-center study in 46 FL patients coordinated by the Fred Hutchinson Cancer Research Center [44] noted a high 42% rate of NRM driven, in large part, by use of mismatched unrelated allografts. Relapse rate at 3 years was low at 14%.

**Allo-HCT for R/R FL: Retrospective Studies**—The NCCN compared outcomes in 48 allo-HCT recipients to patients receiving auto-HCT. [45] The allo-HCT recipients had a 3-year NRM of 26%; in a multivariable analysis, allo-HCT was associated with an increased risk of death compared to auto-HCT (p=0.002). There should be caution in interpretation of these data, however, as the group of FL patients who underwent allogeneic transplantation were a highly select and high-risk group. In contrast, a recent and larger analysis by the CIBMTR indicates that long-term remission is feasible in a significant number of R/R FL patients who receive allo-HCT, and that patients who do not die early in the post-transplant course have prolonged survival compared with patients receiving autologous transplant. Among 268 relapsed patients with grade 1–2 FL who underwent RIC allo-HCT, the 5-year NRM was 26%, the probability of disease progression at 5 years was 20%, and the 5-year PFS was 41%, representing a subset of patients who are likely cured of their disease. The 5-year OS was 66%, and among 24-month survivors, the subsequent risk of death was
decreased for patients receiving allogeneic transplantation compared to those receiving autologous transplants (RR 2.09, p=0.04). [46] A recent retrospective study from Memorial Sloan-Kettering compared outcomes for R/R FL patients undergoing auto-HCT versus allo-HCT in the post-rituximab era. In subgroup analysis was performed in patients who had a remission duration of <12 months prior to salvage therapy, 3 year event-free survival was 42% with auto-HCT versus 80% for allo-HCT, suggesting that patients with a very short first remission (less than 1 year) may be better served with an allo-HCT approach. [47]

**Allo-HCT for grade 3 FL**—A recent report from the CIBMTR examined the outcomes of 61 patients who underwent RIC allo-HCT for grade 3 FL. [48] At 5 years, NRM was 27% and OS 54%, indicating that grade 3 histology should not be an exclusion factor for allo-HCT, and that RIC conditioning can offer long-term survival for patients with grade 3 histology.

**Summary – FL**

While auto-HCT is not considered a curable intervention for most patients, a subset (~30–35%) may enjoy long-term (>5 year) remissions with this therapy, justifying its use in 2nd or 3rd remission. Furthermore, given the development of less toxic, novel therapeutic strategies in the modern era, the use of auto-HCT may decline in the coming years. It should be noted that these novel strategies are not currently known to be curative. In contrast, allo-HCT repeatedly has been shown to be a curative therapy for a significant subset of patients with R/R FL. While the rate of early death is increased among FL patients receiving allo-HCT due to increased NRM, the studies cited above demonstrate excellent long-term outcomes in those surviving the early period. With the increasing application of RIC allo-HCT, and continued improvement in supportive care, NRM rates likely will continue to decline for well-selected FL patients who receive expert supportive care. Such patients can expect a reasonable chance of being cured. These observations apply to patients over age 65 years, for whom outcomes with RIC are comparable to, or only minimally less favorable than, those in the 55–64 year age group. [19]

**MANTLE CELL LYMPHOMA (MCL)**

**Overview of MCL and non-transplant options for frontline therapy**

MCL comprises ~6% of newly diagnosed NHL. Median age at diagnosis is in the late 60s, with a 4:1 male predominance. Patients often present in advanced disease stage along with extranodal involvement. Modern chemoimmunotherapies alone, or as induction followed by auto-HCT in first remission, undoubtedly have improved patient outcomes; however, disease relapse eventually occurs for nearly all patients. [49]

Although variables such as histology (e.g. blastoid morphology), tumor proliferation index, cytogencetics, gene expression profiling, and microRNA expression profile have prognostic value in MCL, their clinical application as a risk stratification tool remains limited. [45] The MCL International Prognostic Index (MIPI) is a commonly used risk-stratification score based on patient age, performance status, serum LDH, and white blood cell count at diagnosis, with/without Ki-67 proliferation index, that classifies MCL into low,
intermediate, and high risk groups with median OS ranging from 29 months to > 5 years. [50] This index also has also been validated to predict outcomes after auto-HCT [51], but has not yet been validated as a tool to direct optimal consolidation therapies in patients responding to frontline therapies.

Using conventional frontline therapy such as R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone), the median remission duration historically was only 12–18 months. [52] Recently, however, incorporation of agents such as bortezomib, bendamustine, and lenalidomide into first-line therapy have improved upon this result, with PFS in the 27–35 month range or longer. [30,53–55] Intensive regimens like R-Hyper-CVAD (rituximab, fractionated cyclophosphamide, vincristine, doxorubicin, dexamethasone alternating with methotrexate and cytarabine) without subsequent consolidation led to impressive PFS in some reports, but toxicity concerns have dampened enthusiasm for this approach. [56–58]

Given the relatively short remissions observed in MCL, investigators have tested the concept of maintenance rituximab after conventional frontline therapies; median duration of first remission has improved to the 3–5 year range. As a result, rituximab maintenance is a reasonable option for elderly MCL patients who are not candidates for HCT. [59,60]

**Auto-HCT for MCL**

**Auto-HCT in first remission**—In the pre-rituximab era, the poor prognosis seen in relapsed MCL motivated the European MCL Network to conduct a randomized, prospective post-remission trial comparing auto-HCT versus interferon-alpha maintenance. [61] Auto-HCT demonstrated superior PFS; however no OS benefit was seen, potentially due to crossing over of the interferon-alpha-treated patients to subsequently receive auto-HCT off protocol. While similar prospective randomized data in the rituximab era are not available, several large prospective phase 2 trials applying up-front auto-HCT after various intensive induction regimens have yielded median PFS durations in the 5–7 year range. [62–67] Despite the lack of randomized, controlled data demonstrating a survival benefit with auto-HCT as consolidation in first remission, many clinicians have adopted this approach. Certain patients such as those not in CR at the time of up-front autoHCT [68], those with minimal residual disease pre-transplant, [69] or those with high-risk MIPI score [51,64,70] fare considerably less well with upfront auto-HCT consolidation, underscoring the need for novel modalities to consolidate first remission for such patients.

**Autologous Transplantation for Relapsed/ Refractory MCL**—Initial retrospective studies, including a European Group of Blood and Marrow Transplantation (EBMT) study, [71] suggested that auto-HCT may have limited value in relapsed and refractory patients. More recent studies, however, including a large retrospective study from the CIBMTR, indicated that durable remissions in the 2–4 year range may be observed for select MCL patients whose disease remains chemosensitive. [68,72] Therefore, in relapsed MCL patients with chemosensitive disease, who are not candidates for a potentially curative allogeneic-HCT (due to co-morbidities, donor availability etc.), consolidation with an auto-HCT can be offered, with the understanding that this therapy is not curative. It remains to be seen
whether auto-HCT will remain part of the treatment paradigm for R/R MCL in the era of new and novel agents.

**Allo-HCT for MCL**

**Allo-HCT in first remission**—Although adoptive immunotherapy in the form of allo-HCT is a potentially curative option for MCL patients, there are no prospective data assessing this approach in first remission. Registry data from the CIBMTR examining the role of allo-HCT versus auto-HCT in first CR or partial remission (PR) showed no benefit in terms of PFS (55% vs. 52% at 5 years) or OS (62% vs. 61% at 5 years); however, early allograft was associated with a significantly higher NRM (25% vs. 3% at 1 year). [68] As a result, use of allo-HCT in chemosensitive MCL patients in first remission generally is not recommended. Early use of allo-HCT can be considered in selected cases for which the chance for success with auto-HCT is poor, such as those with high MIPI score, or those not in CR prior to transplant. It has been hypothesized that the outcome of such patients might be improved by early allografting. This approach would not yet be considered standard care by most clinicians, but warrants prospective investigation.

**Allo-HCT for R/R MCL**—As shown in Table 3, evidence from several single-center studies and large transplant registries have established that allo-HCT is the only potentially curative modality for R/R MCL, with 35–45% of patients disease-free (and likely cured) 3 years post transplantation [68,73–77] Chemosensitive disease and adequate performance status are predictive of improved allo-HCT outcomes. In recent years, the wider adoption of RIC regimens has extended transplant availability to elderly patients and those with medical comorbidities. The challenging subset of MCL patients with chemotherapy-unresponsive disease, however, have a particularly poor prognosis. A large CIBMTR analysis restricted to such chemorefractory patients showed that approximately one-quarter gain durable disease control with allo-HCT, likely due to a clinically relevant GVL effect. [73] No benefit of MA conditioning was seen even in this high-risk cohort of patients. In otherwise healthy patients with relapsed or refractory MCL and an available sibling or adult unrelated donor, an allo-HCT with curative intent is therefore a reasonable therapeutic option. Advanced age, in medically fit patients without significant comorbidities, should not be considered a contraindication.

**Summary – MCL**

Currently, both auto-HCT and allo-HCT play important roles in the management of MCL patients. Auto-HCT is not considered curative therapy for MCL, although intensive induction and consolidation using auto-HCT may provide many patients with remissions that can last 6–8 years or longer. Select MCL patients who did not undergo auto-HCT as part of frontline therapy may also benefit from auto-HCT later in the disease course. Despite the recent emergence of several exciting new agents, for the vast majority of R/R MCL patients, allo-HCT remains the only treatment option with curative potential. With the widespread implementation of RIC, properly selected MCL patients who receive expert supportive care have a reasonable chance of being cured with allogeneic transplantation. This also applies to patients over age 65, for whom outcomes with reduced-intensity conditioning are comparable to those in the 55–64 age group. [19]
Tables 1–3 display many key studies that utilize allo-HCT in DLBCL, FL, and MCL. Several of these reports include patients up to age 70–75 years. One recent registry study by McClune et al specifically analyzed outcomes for patients over age 65 undergoing allo-HCT for lymphoma. \[19\] In this study, 82 elderly NHL patients underwent allo-HCT. While 100 day NRM was not significantly different for the age ≥65 group, NRM at 1 year was higher for the older age group (34%) versus two younger populations, e.g. age 40–54 years (27%) and age 55–64 years (22%). Relapse rates at 3 years were similar across the 3 age groups (28–33%). Not surprisingly, OS was highest in the age 40–54 patients; however the patients ≥65 years old fared reasonably well with OS of 39% at 3 years. However, it bears emphasizing that, for an individual patient over age 65, the real question should not be whether allo-HCT outcomes are comparable to patients under age 65. Rather, the question should be whether allo-HCT offers the best and reasonable chance for long-term remission or cure for that patient, when considering all treatment options.

Due in part to the advances in patient selection, donor selection, pre-transplant lymphoma therapy, and peri-transplant supportive care, older patients are increasingly undergoing allo-HCT. As shown in Figure 1, data from the CIBMTR database show a greater use over time of allo-HCT for NHL patients over age 60 years. For example, for the time period of 2006–2010 the percentage of patients undergoing allo-HCT over age 60 for DLBCL, FL, and MCL were 22%, 23%, and 42%, respectively. Those percentages increased during the next time period (2011–2014) to 31%, 28% and 48%, respectively (personal communication, Center for International Blood and Marrow Transplant Research). These figures clearly demonstrate that for DLBCL, FL and MCL, allo-HCT represents an important therapeutic option, even for older patients. In recent years, alternative donor transplantation (umbilical cord blood or haploidentical marrow) has become more widespread, with recent publications showing outcomes that compare favorably to those using matched unrelated donors. \[78,79\] The haploidentical approach, with post-transplant cyclophosphamide, has successfully been applied to lymphoma patients up to age 75, with 1 year NRM of 10–15% across all age groups from 50–75, and a 3 year survival of approximately 50%. \[80\] With the growing use and success of alternative donor transplantation, it is expected that an even larger number of older patients will be allo-HCT candidates, since in many cases such patients do not have a matched sibling who is in good enough health to serve as a donor.

Based on the data presented above, it is therefore increasingly clear that allo-HCT is in fact feasible in older patients. Transplant clinicians will therefore be increasingly challenged to consider allo-HCT for these older patients. On an individual patient level, deciding to proceed with transplant requires a careful consideration of patient issues (co-morbidities, performance status), disease factors (histology and biological features of the lymphoma, clinical aggressiveness, disease burden), and donor factors. These considerations are of particular importance in older patients where the therapeutic window for transplant may be narrow, and the risk for toxicity and disability post-transplant may be higher. With this in mind, it will be very important to prospectively collect quality of life data in elderly NHL patients undergoing allo-HCT, if allo-HCT becomes a covered indication in these patients.
SUMMARY AND CONCLUSIONS

Ideally there would be more prospective randomized clinical trial data to prove superior survival with allo-HCT for FL, DLBCL, and MCL, compared to alternative approaches. To date no such studies have successfully been completed. One such study was attempted in FL but due to poor accrual was not successfully completed. [81] While it is true that a number of exciting targeted, biological, and immunological therapies are emerging in NHL, it is currently unclear how these new therapies might enhance or replace allo-HCT. High quality studies comparing novel agents with allo-HCT, or integrating such agents with allo-HCT will need to be completed to answer such questions. In the meantime, based on the extensive literature currently available and summarized in this review, it is clear that for many NHL patients, allo-HCT is the only currently available therapy which offers cure.

Advances in the HCT field have enabled this therapy to be applied successfully to patients over age 65 years. Access to allo-HCT in the U.S. has historically been quite limited due to a lack of insurance coverage. Despite this, there is now a body of evidence to show that lymphoma patients in the 60s and 70s can in fact tolerate and benefit from allo-HCT. Based on the evidence, we strongly assert that allo-HCT now represents a standard of care for older NHL patients and, as a result, the associated costs should be covered by insurance carriers.
