Full suppression of antiretroviral therapy (ART) for human immunodeficiency virus type 1 (HIV-1) infection requires the administration of drug combinations that target multiple sites on one or more proteins required for viral replication. Approved antiretrovirals (ARVs) include nucleoside/nucleotide and non-nucleoside reverse transcriptase inhibitors (NRTIs and NNRTIs, respectively), protease inhibitors (PIs), entry inhibitors, and integrase strand-transfer inhibitors (INSTIs). With the exception of the NRTIs, which require intracellular phosphorylation, plasma drug concentrations are correlated with drug efficacy. At the same time, high drug concentrations are associated with excess toxicity.

To durably suppress HIV replication in infected patients, ART concentrations must reach and be maintained at levels that exceed the susceptibility of the virus to that drug. Treatment response is often hampered by the failure to achieve sufficient drug exposure (i.e., poor adherence and drug interactions), reduced drug susceptibility (i.e., viral drug resistance), or both. Drug concentrations within patients vary over time and, due to ease of sampling, are generally characterized by minimum (trough) concentrations (C_{trough}) immediately prior to administration of the next scheduled dose. Drug concentrations also vary considerably between individual patients as a result of differences in absorption, distribution, metabolism, and excretion. In addition, each drug characteristically binds to human plasma proteins to different extents. Furthermore, the susceptibility of HIV-1 variants, even in patients not previously exposed to drug therapy, varies over a range that is unique to each drug (23, 24, 46).

In vitro clinical pharmacodynamic data are available for some, but not all, ARVs. Efficient collection of these data is difficult and ideally performed early in the drug development process. Alternative methods of incorporating ARV pharmacokinetics into therapeutically decision making are being explored. In vitro phenotypic drug susceptibility testing of individual patient viruses is now widely available and generates information that can be used to calculate an inhibitory quotient (IQ), defined as the ratio between the C_{trough} and the drug concentration that inhibits in vitro replication by a defined percentage (e.g., 50% or 95% inhibitory concentration [IC_{50} or IC_{95}, respectively]) (27, 35, 43, 56). Derivatives of the IQ, including the genotypic IQ (GIQ; C_{trough} divided by the number of resistance-associated mutations for a given drug) have also been evaluated (36). Several studies have attempted to define the optimal IQ required to produce long-term viral suppression: in some cases, IQ has been retrospectively linked to clinical outcome (15, 34, 41, 42, 55), while in others, direct relationships between IQ and viral load response were not observed (5, 12).

For most ARV drugs, few or no in vivo concentration-response data have been generated, or these data are inconsistent with clinical observations. Collectively, there is insufficient agreement in the field regarding the determination of the optimal ARV target trough concentrations in the absence of concentration-response data. We conducted the present study to address this deficiency by (i) assessing the activity of PIs, NNRTIs, and an INSTI in a standardized in vitro phenotypic drug susceptibility assay (Phe-

Materials and Methods

Determination of drug activity in the presence of human serum. The PhenoSense HIV assay (Monogram Biosciences, South San Francisco, CA) was performed as described previously (47), with the following modifications. For all PIs except darunavir and atazanavir, each drug was prepared at 10 times the final concentration using complete medium containing 10% fetal bovine serum (FBS) without HS. Fifteen microliters of the 10× drug stocks was mixed with 85 μl of complete medium containing 10% FBS and 0%, 25%, 50%, or 75% pooled HIV-negative HS or 90% HS plus 10% FBS in 96-well plates. Fifty microliters of trypsinized, transfected (virus-producing) cells was added to the plates containing 10 μl drug and medium, which had been resuspended in the corresponding medium (i.e., with or without HS at 25 to 90%). Thus, the concentration of HS present during virus particle formation was 22.5%, 45.0%, 67.5%, or 81%; FBS was present at 10% for all conditions. Viral stocks were harvested approximately 48 h after transfection, and 100 μl was used to infect fresh 293 cell cultures (target cells) that had been plated in a volume of 50 μl in medium containing 10% FBS. During the period of time when darunavir and atazanavir were evaluated, several modifications to the PhenoSense assay were implemented, resulting in subtle differences in final HS concentrations compared to the procedure described above. These changes resulted in final HS concentrations during virus production of 21.7%, 43.5%, 65.2%, or 76.5%. For the purposes of this report, these minor differences (3 to 6%) in final HS concentration were ignored relatively constant, while the IC50s for most other drugs increased incrementally. Since the relationship between IC50 and HS concentration for most drugs was fairly linear between 23 and 81% HS, the IC50 at 100% HS was estimated using linear regression. Approximately 72 h after infection, target cells were lysed and luciferase activity was measured to assess virus replication in the presence or absence of drugs at each concentration of HS. IC50 and IC95 values were determined as described previously (47). Between 2 and 32 (mean, 8.5) replicates of susceptibility assays were performed for each virus, using either a drug-sensitive reference virus (NL4-3) and a well-characterized multidrug-resistant reference virus (MDRC-4) that exhibits reduced susceptibility to at least one drug and medium, which had been resuspended in the corresponding medium (i.e., with or without HS at 25 to 90%). Thus, the concentration of HS present during virus particle formation was 22.5%, 45.0%, 67.5%, or 81%; FBS was present at 10% for all conditions. Viral stocks were harvested approximately 48 h after transfection, and 100 μl was used to infect fresh 293 cell cultures (target cells) that had been plated in a volume of 50 μl in medium containing 10% FBS. During the period of time when darunavir and atazanavir were evaluated, several modifications to the PhenoSense assay were implemented, resulting in subtle differences in final HS concentrations compared to the procedure described above. These changes resulted in final HS concentrations during virus production of 21.7%, 43.5%, 65.2%, or 76.5%. For the purposes of this report, these minor differences (3 to 6%) in final HS concentration were ignored relatively constant, while the IC50s for most other drugs increased incrementally. Since the relationship between IC50 and HS concentration for most drugs was fairly linear between 23 and 81% HS, the IC50 at 100% HS was estimated using linear regression. The ratio between the estimated IC50 at 100% HS (mimicking the in vivo situation) and the IC50 under standard in vitro conditions is referred to as the PBIC. A PBIC for 45% HS can also be calculated using the experimental data. Table 1 lists the PBIC values for 100% HS and 45% HS derived here, along with the 50% HS correction factors derived in a previous study (40), as well as estimations of protein binding derived from in vitro biochemistry studies as reported by the various drug manufacturers. Correction factors for 45% HS (this work) and 50% HS (40) were highly correlated for the six drugs where both values were available. The PBIC values that were independently determined in both studies also correlated with the magnitude of protein binding for each drug (Table 1). Previously reported PBICs for atazanavir and amprenavir (13.4 and 7.4, respectively) are similar to the values reported here, in spite of the fact that these older studies used only purified α-1 acid glycoprotein and human serum albumin and not complete serum (14, 48).

To derive in vivo target trough concentrations for patients infected with drug-susceptible virus, PBICs were applied to mean IC50 and IC95 values from clinically derived HIV-1 strains. Over 6,500 results from viruses lacking detectable amino acid substitutions that are nonpolymorphic and selected under ARV drug pressure (46) were identified in a database of linked phenotypic and genotypic assay results. Fewer results were available for raltegravir (n = 1,200). The total plasma drug concentration expected to inhibit wild-type virus in vivo by 50% (PBIC50) or 95% (PBIC95) was calculated from these data (Table 2). Although it is not known whether the PBIC50 or PBIC95 most accurately reflects the optimal target trough concentration for these agents, the given the consider-
able inter- and intrapatient variability in $C_{\text{trough}}$, a conservative approach is to use the highest of these (i.e., the PBIC95). The corresponding optimal IQ95 ($C_{\text{trough}}$ divided by PBIC95) for an effective ARV drug should thus be 1 or greater. In fact, this is the case for all of the drugs that we examined except nelfinavir (IQ95 = 0.26). For comparison, the currently proposed target drug concentrations from the Department of Health and Human Services (DHHS) guidelines (45) are also listed in Table 2.

**DISCUSSION**

The results generated in this study add to the current body of knowledge relating ARV drug target trough concentrations to drug efficacy and more specifically demonstrate the importance of serum protein binding when relating *in vitro* drug susceptibility measurements to plasma drug concentrations. As expected, the ARV drugs that exhibit the lowest levels of protein binding (indinavir, amprenavir, atazanavir, nevirapine, and raltegravir) have the smallest PBCFs (Table 1). Notably, lopinavir also has a relatively low PBCF, despite reports of high (98 to 99%) serum protein binding. This apparent discrepancy has been reported by others and may be attributed to differential binding properties of bovine serum proteins in the tissue culture medium (26, 28).

The PBCFs reported here agree well with values previously published by Molla et al. for the subset of PIs that were tested in both studies (40). This earlier study employed a multiple-replication-cycle inhibition assay using MT4 cells, HIV-1 IIIB, and a colorimetric readout for cytopathic effects. In contrast, our study was conducted using a single-cycle inhibition assay, replication-defective recombinant viruses, and a luciferase reporter readout (47). Our methodology permits assessments of protein binding effects on drug susceptibility measurements at higher HS concentrations than replication-competent systems because of the shorter period of time that cells are in contact with high HS concentrations (2 to 3 days). In most cases, we were able to assess drug susceptibility in the presence of 81% HS, although the luciferase signal was considerably reduced at this high concentration.

Our results for several PIs are also consistent with previously derived *in vivo* pharmacokinetic/pharmacodynamic relationships, particularly amprenavir, indinavir, and saquinavir. In a dose-finding study of amprenavir, a fitted sigmoid maximum effect ($E_{\text{max}}$) curve between amprenavir $C_{\text{trough}}$ and HIV-1 RNA response demonstrated a significant relationship (51). The plasma concentration required to produce 50% of the maximum response ($E_{\text{50}}$) was 87 ng/ml. By using the reported Hill coefficient, we were able to estimate the $E_{\text{50}}$ (320 ng/ml) value as well. Current DHHS guidelines recommend an amprenavir target $C_{\text{trough}}$ of 400 ng/ml (45). Using the PBCF determined in this study, our estimate of amprenavir PBIC95 is 358 ng/ml (Table 2), which is strikingly similar to the recommended $C_{\text{trough}}$ value.

In a small subset of pediatric patients receiving indinavir, stavudine, and didanosine, a significant inhibitory $E_{\text{max}}$ relationship between the indinavir $C_{\text{trough}}$ and change in HIV-1 RNA from baseline to week 24 was described (16). The maximum reduction in HIV-1 RNA (2.0 log_{10} copies/ml) corresponded to an $E_{\text{sat}}$ of 80 ng/ml. In a separate study in adult patients treated with indinavir in combination with zidovudine and lamivudine, the indinavir $C_{\text{trough}}$ levels at week 4 were significantly associated with changes in HIV-1 RNA from baseline to week 4 (42). Based on an $E_{\text{max}}$ model, an $E_{\text{50}}$ was estimated to be 110 ng/ml. Current DHHS guidelines recommend a target $C_{\text{trough}}$ of 100 ng/ml (45). We estimated the indinavir PBIC95 to be 73 ng/ml (Table 2), which again is similar to *in vivo* estimations.

A significant correlation between saquinavir $C_{\text{trough}}$ and sustained viral load suppression has been observed in children (21). The minimum mean saquinavir $C_{\text{trough}}$ associated with durable viral load suppression was 200 ng/ml. Additional support for this target comes from the modeling of saquinavir pharmacokinetics/pharmacodynamics following saquinavir monotherapy in HIV-positive patients (18). Following administration of 1,200-mg saquinavir three times daily (soft gel formulation), both area under the curve (AUC) and $C_{\text{trough}}$ measures were related to peak reduction in plasma HIV-1 RNA. The median 24-h AUC (AUC_{24})

**FIG 1** Effect of human serum on *in vitro* drug susceptibility. Shown are representative PhenoSense inhibition curves demonstrating the effect of addition of human serum at 22.5% (red diamonds, solid line), 45.0% (green diamonds, solid line), or 67.5% (red squares, dotted line), compared to standard (10% FBS) conditions (blue squares, dotted line). The drug-susceptible (NL4-3) reference virus was used. (A) Darunavir (DRV); (B) efavirenz (EFV); (C) raltegravir (RAL). Vertical dotted lines denote the IC50.
was 20 μg · h/ml, which corresponded to 85% of the maximum effect (EC85); the C_{trough} at this dose was 216 ng/ml (18). Current DHHS guidelines recommend a target C_{trough} of 100 to 250 ng/ml (45). We calculated the saquinavir PBIC95 to be 234 ng/ml (Table 2), which is highly concordant with clinically established values.

There is controversy regarding the optimum C_{trough} for efavirenz. The reported therapeutic range (lower to upper exposure targets) for efavirenz is 1,000 to 4,000 ng/ml (37). These data come from a study that explored the relationships between EFV exposure, efficacy, and development of central nervous system (CNS) side effects. Since the discordance between this pharmacodynamic study and our in vitro results is considerable, it is worth noting that this was an exploratory field trial in which all patients received the same EFV dose and was not a well-controlled, broad-dose-ranging study. In addition, EFV concentrations were determined using blood samples that were collected on average 14 h postdosing (range of 8 to 20 h postdosing). Although EFV has a relatively long half-life, actual C_{trough} values were not determined or estimated. Furthermore, treatment adherence was not considered, which may account for the broad range of EFV concentrations (125 to 15,230 ng/ml) that were observed. Mutations in cytochrome P450 (CYP) 2B6 are also associated with EFV exposure (22), but in the absence of race/ethnicity data, it is not possible to infer the contribution of genetics to the interpatient variability in EFV concentrations in the study. Also, as discussed by the authors, there was considerable overlap in EFV concentrations among patients that experienced treatment failure versus those that did not. Finally, drug concentrations were determined 3 to 18 months after initiation of EFV therapy—well past the time at which EFV-associated neurologic symptoms have been correlated to plasma concentra-
tions (10). Our estimation of the PBIC95 for efavirenz is 126 ng/ml, which is well below the average Ctrough of 1,800 ng/ml in patients receiving 600 mg once daily and below the proposed EFV lower concentration threshold (1,000 ng/ml). The decay rate of EFV relative to its PBIC95 in one patient who discontinued treatment with EFV, stavudine, and lamivudine has been described (49). In this patient, plasma HIV-1 RNA level was <50 copies/ml at the time of treatment discontinuation and viral rebound was detected 21 days later—coincident with the time that the EFV plasma concentration fell below 50 to 100 ng/ml. Although these data represent a single patient, they suggest that the target EFV Ctrough may be well below 1,000 ng/ml and are consistent with our estimation of EFV PBIC95 described here. In light of these findings, reevaluation of the generally accepted therapeutic concentration range of 1,000 to 4,000 ng/ml for EFV seems warranted.

In vivo exposure-response relationships for a number of the ARVs are not well defined. Suggested Ctrough targets for some of these agents are based either on in vitro susceptibility data alone or studies that compare plasma drug concentrations to virologic outcomes (30, 31). For example, in the HIV-NAT 017 study, virologic outcome was assessed in PI-naïve children treated with lopinavir/ritonavir (230/57.5 mg/m²) plus saquinavir (50 mg/kg) twice daily (4). The 2 children with a lopinavir Ctrough of <1,000 ng/ml both experienced virologic failure (HIV RNA of >400 copies/ml) at week 24, compared to a single virologic failure among the remaining 17 children with a lopinavir Ctrough of >1,000 ng/ml. This finding suggests that the target Ctrough of lopinavir is approximately 1,000 ng/ml in PI-naïve patients. Similarly, plasma drug concentrations and the risk of virologic failure were evaluated in a cohort of 189 HIV-infected, NNRTI-naïve patients treated with standard dose nevirapine in combination with other agents (13). In multivariate analysis, a nevirapine plasma concentration of less than 3,000 ng/ml was associated with a 5-fold increased risk of

d—Protein binding correction factor at 100% HS, extrapolated from the experimental data described above.
}

For details, see reference 45. NA, not applicable because no target drug concentration has been determined for PI-naïve patients. For PI-experienced patients, the recommended Ctrough for darunavir, tipranavir, and etravirine are 550, 20, 500, and 52 ng/ml, respectively (45).
virologic failure, suggesting that a nevirapine $C_{\text{trough}}$ of 3,000 ng/ml or greater should be maintained to obtain optimum virologic outcomes. Using similar approaches, target $C_{\text{trough}}$ values of 150 ng/ml and 2,500 ng/ml, respectively, have been proposed for ritonavir-boosted atazanavir (atazanavir/r) and tipranavir (tipranavir/r) (20, 44); however, neither study was sufficiently powered to define threshold therapeutic concentrations. These values are higher than the PBIC$_{95}$ measures that we determined in this study (60 ng/ml and 3,902 ng/ml, respectively) (Table 2). One possible explanation is related to the use of cohort studies, which are likely to include intermittently adherent patients, to define minimum effective $C_{\text{trough}}$ values for antiretroviral drugs. Unlike carefully conducted, wide-dose-ranging pharmacokinetic/pharmacodynamic studies, target drug concentrations estimated from cohort studies are based on variations in interpatient concentrations for a given dose administered to many individuals. Consequently, this approach generates insufficient data to accurately populate the low end of a true concentration-response curve and will tend to overestimate the threshold drug concentrations.

The PBIC$_{95}$ calculated for nelfinavir (3,865 ng/ml) in this study is considerably higher than the measured (1,000 ng/ml) or recommended target (800 ng/ml) $C_{\text{trough}}$ (45). This discrepancy may be at least partly explained by the observation that nelfinavir is metabolized in the liver, producing metabolites, including M8 (32), which itself exhibits antiviral activity comparable to that of the parent drug (57). M8 concentrations approach 30% of the parent drug concentration, and this metabolite exhibits slightly less serum protein binding than nelfinavir (57). Since nelfinavir is not metabolized to M8 in vitro, our estimate of the nelfinavir PBIC$_{95}$ in this study is likely higher than the true in vivo value, and thus the effective IQ$_{95}$ is likely to be underestimated.

The IQ$_{95}$ for raltegravir (1.2) is lower than expected for a highly efficacious drug. A recent presentation reported a median plasma $C_{\text{trough}}$ in healthy volunteers of 82 ng/ml ($n = 45$), which agrees well with our estimates of PBIC$_{95}$ but is 30% higher than the value reported on the drug label (33). In vitro studies have shown that dissociation of raltegravir from the preintegration complex occurs more slowly than dissociation of the preintegration complex itself, meaning that raltegravir binding is essentially irreversible (25). Results from a 48-week once-daily (800-mg) versus twice-daily (400-mg) raltegravir study (50) showed that the once-daily arm was virologically inferior to the twice-daily arm. The average 12-h concentration ($C_{12}$), derived from intensive pharmacokinetic assessments, was 257 nM (114 ng/ml) in the 400-mg twice daily group versus 40 nM (17.8 ng/ml) in the 800-mg once-daily group. Our results indicate that the raltegravir PBIC$_{95}$ is 94 ng/ml (211 nM), which may in part explain why the once-daily group was inferior. Relationships between $C_{\text{trough}}$ and HIV-1 RNA response for two additional INSTI candidates have been demonstrated in wide-dose-ranging early phase monotherapy trials (11, 52).

The application of in vitro susceptibility data to in vivo PBIC$_{95}$ predictions has several limitations. The HS conditions used in the infectivity assays described here may not accurately mimic the situation in vivo (i.e., drug binding in human blood). Inter- and intraindividual variabilities in binding protein concentration encountered in vivo are not taken into account using this approach. However, our study was performed using two lots of HS, each pooled from multiple donors, to minimize the possibility of lot-specific artifacts. In addition, in vitro determinations of IC$_{50}$ or IC$_{95}$ values for individual drugs do not capture synergistic, antagonistic, or additive effects among different drugs that may occur in vivo. Furthermore, the use of a simple linear regression model to extrapolate PBCFs for 100% HS from the experimentally determined IC$_{50}$ in the presence of 23 to 81% HS may not be equally applicable to all drugs. Most importantly, there is a paucity of in vivo pharmacodynamic data with which our results can be validated.

Collectively, the available in vivo concentration-response data, which are considered the “gold standard” from the pharmacodynamic perspective, correlate strikingly well with the PBIC$_{95}$ values we have derived from in vitro susceptibility and PBCF measurements, with the exceptions of the cohort studies described above. Consequently, we propose that this parameter is an appropriate surrogate measure of target $C_{\text{trough}}$ for antiretroviral drugs (excluding those that require intracellular activity [i.e., NRTI]) in lieu of formal early phase pharmacodynamic assessments. Ideally, concentration-response relationships for ARV drugs should be defined early in the development process. Phase III trials (or phase IV postmarketing studies) are not the appropriate time to define drug target concentrations because their design requires that all participants receive either one given dosage or one of several dosages within a narrow range. Late phase I or early phase II trials should incorporate wide dose-finding designs encompassing dosages that exceed 10-fold differences (preferably larger) in order to adequately populate concentration-response curves. In the absence of clearly defined concentration-response relationships, identification of precise target drug exposure is not possible.

The derivation of PBCFs that can be applied to IC$_{50}$ data generated by routine phenotypic assays such as PhenoSense HIV also provides a useful way to relate these in vitro concentrations to total in vivo drug exposure for applications that include therapeutic drug monitoring and calculation of IQ values for viruses with reduced drug susceptibility.

**ACKNOWLEDGMENTS**

We gratefully acknowledge the contributions of the Monogram Clinical Reference Laboratory for performing the PhenoSense and GeneSeq assays and Moigan Haddad (Monogram Biosciences) for assistance with retrieval of IC$_{50}$ and IC$_{95}$ data from the Monogram database and regression analysis.

Development of the Monogram PhenoSense and GeneSeq integrase assays was supported by a grant from the NIH/NIAID, SBIR-AT 5 R44 AI057074. E.A. is the recipient of NIH grant R01 AI05869.
