Abstract

Fatigue is one of the most common and distressing symptoms, leading to markedly decreased quality of life among a large subset of patients with a variety of disorders. Susceptibility to fatigue may be influenced by genetic factors including single nucleotide polymorphisms (SNPs), especially in the regulatory regions, of relevant genes. To further investigate the association of SNPs with fatigue in various patient populations, a systematic search was conducted on Pubmed, CINAHL, PsycINFO, and Sociological Abstracts Database for fatigue related-terms in combination with polymorphisms or genetic variation-related terms. Fifty papers in total met the inclusion and exclusion criteria for this analysis. These 50 papers were further classified into three subgroups for evaluation: chronic fatigue syndrome (CFS), cancer-related fatigue (CRF) and other disease-related fatigue. SNPs in regulatory pathways of immune and neurotransmitter systems were found to play important roles in the etiologies of CFS, CRF and other disease-related fatigue. Evidence for associations between elevated fatigue and specific polymorphisms in TNF\textsubscript{\textalpha}, IL1\textbeta, IL-4 and IL-6 genes was revealed for all three subgroups of fatigue. We also found CFS shared a series of polymorphisms in HLA, IFN-\gamma, 5-HT and NR3C1 genes with other disease-related fatigue, however these SNPs (excluding IFN-\gamma) were not found to be adequately investigated in CRF. Gaps in knowledge related to fatigue etiology and recommendations for future research are further discussed.

Appendix A. Supplementary data
Supplementary data associated with this article can be found, in the online version, at http://dx.doi.org/10.1016/j.bbi.2017.01.007.
1. Introduction

Fatigue is a common symptom whose descriptors include tiredness, weakness, lack of energy, and inability to concentrate (Landmark-Hoyvik et al., 2010). Among studies investigating symptom prevalence, fatigue consistently ranks among the top three symptoms reported by patients with a variety of diseases (Wessely, 2001). Fatigue symptoms can have a negative effect on social relationships, mental health, and daily activities, causing a marked decrease in overall quality of life both during illness and after treatment (Bower, 2014; Bower et al., 2013). For the purposes of further understanding the etiology and pathophysiology of fatigue, fatigue symptoms can be categorized into three major subgroups: chronic fatigue syndrome (CFS), cancer-related fatigue (CRF), and other disease-related fatigue.

Following standard guidelines, CFS is a chronic, disabling disorder that is defined as six months of disabling fatigue that cannot be explained by an underlying condition. A diagnosis of CFS also requires at least four of the following eight possible accompanying symptoms: impaired memory or concentration, sore throat, tender cervical or axillary lymph nodes, muscle pain, pain in several joints, headaches, unrefreshing sleep, or malaise after exertion (Fukuda et al., 1994; Reeves et al., 2003). Although CFS has a relatively low prevalence (0.3–2.5%) in the general population (Prins et al., 2006), disease-related fatigue is one of the most common symptoms of cancer, infectious diseases, cardiovascular diseases, and autoimmune disorders as well as their related treatments. Disease-related fatigue may be acute (such as in response to an infection) or chronic, persisting for years, even after treatment completion (such as in a chronic medical condition or ongoing fatigue after resolution of an infection) (Allen et al., 2008; Becker et al., 2015; Bower, 2014; Helbig et al., 2003). Cancer-related fatigue (CRF) is defined as a distressing, persistent, subjective sense of physical, emotional, and/or cognitive tiredness or exhaustion related to cancer and/or its treatment that is not proportional to recent activities and interferes with usual functioning (Bower, 2014). Of fatigue related to disease, CRF has been extensively investigated, perhaps due to its high prevalence (25–99%), severity, persistence, and debilitating effects (Bower et al., 2013; Reinertsen et al., 2011b).

Studies suggest that CFS, CRF, and other disease-related fatigue are complex conditions with multifactorial etiology involving multiple mechanisms (Landmark-Hoyvik et al., 2010). Although CFS, CRF, and other disease-related fatigue may be qualitatively and quantitatively different from one another, they may also share biological mechanisms of onset and exacerbation. Previous studies have shown that they all involve both the peripheral nervous system (PNS) and the central nervous system (CNS) (Rovigatti, 2012). In addition, there has been a long-standing interest in the role of the immune system in the pathogenesis and pathophysiology of CFS and CRF, especially the role of inflammatory cytokines.
(Blundell et al., 2015; Saligan et al., 2015). Accordingly, genetic components, such as single nucleotide polymorphisms (SNPs) in immune and neurotransmitter-related genes, have been investigated. SNPs are single base variations in DNA structure that are found in 1% of the population or more (the most common type of genetic variation). They are typically measured by genotyping techniques based on DNA extracted from peripheral blood. SNPs found in the regulatory regions of genes (called functional SNPs), including promoters, introns and untranslated regions, can, in many cases, affect the expression of the related gene products including proteins (Albert, 2011), thereby potentially influencing mechanisms involved in fatigue susceptibility (Reyes-Gibby et al., 2013b).

Polymorphisms specific to the three subgroups of fatigue are not well-established, and no study has identified SNPs common to these subgroups. A systematic review of the available literature may help to elucidate shared etiologies by examining potential common relationships between genetic polymorphisms and the various fatigue subtypes across studies. Moreover, this information may contribute to improved clinical management of fatigue symptoms by avoiding underestimation of prevalence and under-treatment by clinicians (Saligan and Kim, 2012; Vogelzang et al., 1997).

2. Methods

A general literature search was conducted in Pubmed, CINAHL, PsycINFO, and Sociological Abstracts Database, using the following key words: fatigue AND (single nucleotide polymorphisms OR genetic variation). In order to incorporate specific concerns related to cancer-related fatigue, other key words added to the search included: (Cancer OR neoplasms OR tumor OR oncology) AND (gene OR single nucleotide polymorphisms OR genetic variation). Reference lists and bibliographies from published studies were used to find additional articles to review. The search was limited to articles written in English, but there was no limitation on publication year. The titles and abstracts of the articles identified through the search were evaluated by two reviewers (TW and JY), and articles for more extensive review were selected using the following inclusion and exclusion criteria:

Inclusion criteria: 1) clear focus on chronic fatigue syndrome, cancer-related fatigue, or other disease-related fatigue (both acute and chronic); and 2) containing data on any polymorphisms. Studies categorizing subjects as fatigued or not (case-control) and studies examining fatigue as a continuous variable were included.

Exclusion criteria: 1) general reviews, systematic reviews and meta-analysis, editorials, case studies, and non-human studies; 2) studies not focusing on the three types of fatigue; or 3) studies with no data on gene polymorphisms.

Selection of studies to be reviewed involved four steps depicted in Figs. 1 and 2. Data from studies that met inclusion criteria were independently extracted by two reviewers (TW and JY). The data extracted included descriptive information about the study authors, publication year, main goals of the study, clinical pheno-type, number of participants, study design, methods of fatigue assessment, biological end point(s) (specific genes and SNPs), and main findings. Disagreements between reviewers were resolved by consensus or, when necessary,
adjudicated by a third reviewer (CX). The definition of fatigue was based on the criteria of each individual study.

The Newcastle-Ottawa Scale (NOS) was used for assessing the quality of non-randomized studies (Stang, 2010). The NOS recognizes quality indicators in three domains: selection of study groups, comparability of study groups, and exposure and outcome ascertainment. Using this scale, a study could be awarded a maximum of one or two points for each indicator (sample size, inclusion-exclusion criteria, fatigue measurement, HWE assessment, genotype blinding, genotype assessment, statistical method, and confounder assessment) within each assessment domain (selection, comparability, and ascertainment) for a possible maximum total score of 15 points. The assessment of study quality was independently conducted by two reviewers (TW and JY), and the results were compared until a consensus was reached. The full quality assessment criteria are described in detail in the Supplementary Appendix.

3. Results

Fifty articles met our inclusion and exclusion criteria and were categorized into three major subgroups including CFS, CRF, and other disease-related fatigue. For each subgroup, we provided an overview of our findings, related mechanisms, and predicted effects (if applicable).

3.1. Chronic fatigue syndrome

3.1.1. Overview—Sixteen articles on CFS, published between 2003 and 2015, were included in this systematic review based on our inclusionary and exclusionary criteria. The number of cases in these studies ranged from 35 to 171. Two articles did not specify the number of controls (Fukuda et al., 2013; Lee et al., 2009; Smith et al., 2006). All of the studies used 1994 Fukuda criteria as the definition of CFS (Fukuda et al., 1994). Table 1 provides details on the studies related to CFS included in the analyses. The average quality score was 7.5, with scores ranging from 2 to 13. The most common reasons for lower scores were not mentioning genotyping blinding methods and insufficient description of confounders.

3.1.2. Mechanisms—Although the pathophysiological mechanisms for CFS are not clearly identified, the 12 of the 16 studies provided evidence to support gene-related mechanisms of CFS. These mechanisms primarily included neurotransmitter dysregulation (five studies) (Fukuda et al., 2013; Narita et al., 2003; Smith et al., 2008, 2011; Sommerfeldt et al., 2011), hypothalamic-pituitary adrenal (HPA) axis regulation (two studies) (Lee et al., 2009; Rajeevan et al., 2007), inflammatory/immunomodulatory responses (four studies) (Carlo-Stella et al., 2006, 2009; Rajeevan et al., 2015; Smith et al., 2005), and other mechanisms involving metabolism and endurance (one study) (Vladutiu and Natelson, 2004).

3.1.2.1. Neurotransmitter system: The most common neurotransmitter system related to CFS was the serotonergic system. A number of polymorphisms in serotonin transporters, receptors and synthetic enzymes were linked to CFS. In a case-control study (Narita et al., 2003), a polymorphism in the serotonin transporter gene 5’ upstream region (5-HTTLPR)
(rs25531, rs25532) was identified in CFS patients, but not controls. In addition, three markers located in the 5-HT receptor subtype HTR2A (rs1923884, rs6311 and rs6313) were found to be associated with CFS (Smith et al., 2008). Additionally, polymorphisms in the monoamine synthetic enzymes, tyrosine hydroxylase (TH) (rs10770141), which synthesizes dopamine, and GTP cyclohydrolase I (GCH) (rs841), which is involved in the synthetic pathway of all the monoamines, have been associated with the pathophysiology of CFS (Fukuda et al., 2013). Two polymorphisms in the adrenergic signaling pathway, including the β2-adrenergic receptor and catechol-O-methyl transferase (COMT) that catabolizes noradrenaline, were found to be significantly more abundant in CFS patients than in controls; these were the GG genotype of rs1042714 and the AA genotype of rs4680, respectively (Sommerfeldt et al., 2011). Finally, two genes involved in other neurotransmission systems were found to be nominally associated with CFS (Smith et al., 2011), suggesting possible roles for genes involved in glutamatergic neurotransmission (GRIK2 rs2247215) and circadian rhythms (NPAS2 rs356653).

3.1.2.2. Hypothalamic-Pituitary-Adrenal axis: NR3C1, a glucocorticoid receptor gene influential in regulating HPA axis function and blood glucocorticoid (cortisol) concentrations has garnered attention in exploration of the pathological mechanism of CFS. Supporting results were observed in a case-control study conducted by Rajeevan et al. (2007) in this study, four markers of NR3C1 (rs1866388, rs2918419, rs860458 and rs6188) were significantly associated with CFS. Furthermore, in a study using an integrated approach to seek the association between genotype variation and disease, NR3C1 rs1866388, rs852977 and rs258750 were shown to be highly associated with CFS (Lee et al., 2009).

3.1.2.3. Inflammation and immune response: Immune dysregulation and inflammatory reactions may also contribute to CFS. A study focusing on human leucocyte antigen (HLA) class II alleles found a significant association between HLA-DQA1*01 and CFS (Smith et al., 2005). Another study (Carlo-Stella et al., 2009) found that the combination of RAGE-374A (rs1800624), HLA-DRB1*1104 (rs1800625), RAGE-374A, and HLA-DRB1*1301 was associated with CFS, whereas when singly expressed, these variants were not associated with disease. DRB1*1104 was found to be a protective factor when expressed alone. In addition, the cytokine SNP TNF-308 was found to be highly associated with CFS (Carlo-Stella et al., 2006). This relationship was further supported by another study that demonstrated associations between 32 inflammation and immune-related SNPs and CFS (Rajeevan et al., 2015).

3.1.2.4. Other mechanisms: In a case-control study investigating the genetics of muscle metabolism and physical endurance, M647V on gene Decapping Enzyme Homolog (DCP1) was found to be associated with CFS among veterans of the first Persian Gulf War (Vladutiu and Natelson, 2004).

3.1.3. Predicted effect—While most studies aimed to investigate the association between SNPs and CFS, several studies explored the predictive effects of SNPs on CFS. One study (Goertzel et al., 2006) found that 28 SNPs could be used to predict CFS with 76% accuracy.
The majority of relevant SNPs were located in regions of *TPH2, COMT* or *NR3C1*. Another study (Cifuentes and Barreto, 2011) also found a valid profile of 13 SNPs that predicted CFS with 72.8% accuracy. The majority of polymorphisms associated with CFS occurred in 5-HTT and *NR3C1*. Moreover, a previous study (Lin and Hsu, 2009) found that a gene-gene effect involving *NR3C1* and a gene-environment effect of *NR3C1* and gender could play important roles in CFS. To seek clinical diagnostic meaning, Shimosako and Kerr (2014) observed that 21 out of 504 SNPs were significantly associated with CFS/myalgic encephalomyelitis. Most were located in the bone morphogenic protein-2-inducible protein kinase (*BMP2K*) gene, which plays an important role in skeletal development and patterning (Liu et al., 2009), and in the *IL6ST* gene (aka. Glycoprotein 130), which encodes a transmembrane protein as part of the type I cytokine receptor in *IL-6*-receptor family (thereby ensuring correct ligand binding and protein folding) (Hibi et al., 1990).

### 3.2. Cancer-related fatigue

#### 3.2.1. Overview

A total of 16 articles on CRF were chosen based on our inclusionary and exclusionary criteria. Of those 16 articles, 10 were longitudinal studies (Aouizerat et al., 2009; Dhruva et al., 2015; Fernandez-de-las-Penas et al., 2012; Illi et al., 2012; Jim et al., 2012; Miaskowski et al., 2010; Reinertsen et al., 2011a; Reyes-Gibby et al., 2013a, 2013b; Vallance et al., 2010); three were cross-sectional studies (Bower et al., 2013; Collado-Hidalgo et al., 2008; Shi et al., 2015); two were cohort studies (Rausch et al., 2010; Sloan et al., 2012) and the remaining one used a case-control design (Athanasoulia et al., 2012). The studies differed in almost all clinical (e.g., cancer type, therapeutic intervention) and methodological components. More than three quarters (14/16, 87.5%) were published recently (2010–2013). The predominant cancer populations studied were breast and lung cancer. Half of the studies (8/16) enrolled solely breast cancer or lung cancer participants, and the remaining studies enrolled patients with mixed cancer diagnoses other than breast or lung. As might be expected, a wide variety of fatigue instruments was used, including the Lee Fatigue Scale (LFS) (5/16, 31%), Multidimensional Fatigue Symptom Inventory (MFSI) (2/16, 12.5%), 12-Item Short Form Health Survey (SF-12) (2/16, 12.5%), and others (7/16, 44%). All studies assessed fatigue using multi-item questionnaires. The rating scores of the two independent raters using eight quality categories together are shown in Table 2. The overall quality of the studies was moderately high, averaging 10.2. Across the 16 studies, the most common reasons for lower quality scores were not mentioning genotype blinding and insufficient control of confounding factors.

#### 3.2.2. Mechanisms

The genetic polymorphisms under investigations from the above described studies can be grouped into 2 categories: inflammation and immune response (thirteen studies) (Aouizerat et al., 2009; Bower et al., 2013; Collado-Hidalgo et al., 2008; Dhruva et al., 2015; Illi et al., 2012; Jim et al., 2012; Miaskowski et al., 2010; Reinertsen et al., 2011a; Reyes-Gibby et al., 2013a; Reyes-Gibby et al., 2013b; Shi et al., 2015; Sloan et al., 2012) and other mechanisms (three studies) (Athanasoulia et al., 2012; Fernandez-de-las-Penas et al., 2012; Vallance et al., 2010). Genotypes of the following genes were assessed in these 16 studies: interleukin (IL)-1α (*IL-1α*), IL-1β, IL-4, IL-6, IL-10, tumor necrosis factor-α (*TNF-α*), α2-Heremans-Schmid glycoprotein (*AHSG*),...
polymerase delta-interacting protein 3 (POLDIP3), COMT, and ATP binding cassette subfamily B member 1 (ABCB1).

### 3.2.2.1. Inflammation and immune response:

The majority (13/16, 81%) of the identified articles focused on exploring potential immune and inflammatory contributors to CRF. The associations of SNPs in genes IL-1β (rs16944), IL-6 (rs1800795), and TNF-α (rs1800629) with fatigue severity were the most frequently investigated, and these studies yielded mixed results. One study (Collado-Hidalgo et al., 2008) suggested that the prevalence of at least one cytosine mutation in IL1b (rs16944) was substantially greater among fatigued than non-fatigued breast cancer survivors. However, three other recent studies found that the IL1b-511 (rs16944) genotype did not significantly predict changes in fatigue in survivorship (Bower et al., 2013; Jim et al., 2012; Reinertsen et al., 2011a). Two studies observed that GG genotypes of TNFa-308 (rs1800629) and IL-6-174 (rs1800795) were significantly associated with CRF in women with early breast cancer both during and after treatment (Aouizerat et al., 2009; Bower et al., 2013). Another study (Jim et al., 2012) also observed that men with prostate cancer with the IL-6-174 (rs1800795) G/C or C/C genotype and those with the TNFa-308 (rs1800629) genotype showed greater increases in fatigue 6 months after initiation of androgen deprivation therapy. However, after controlling for covariates such as age, race, and baseline depressive symptoms, only the TNF-α genotype remained significantly associated with fatigue severity.

Researchers also studied the association between other SNPs in IL-1β and IL-6 genes and cancer-related fatigue. One study (Rausch et al., 2010) identified 21 SNPs in cytokine genes related to symptom burden and quality of life (QOL) outcomes among 1149 lung cancer survivors. Among the 21 SNPs, they found that IL-1β rs1143633 and rs2853550 were associated with fatigue symptoms. However, no association was found between IL-6 rs41800795 and fatigue. A study on QOL in 168 oncology outpatients and 85 family caregivers (FCs) demonstrated that, along with younger age, being white and being a patient (versus a FC), the minor allele of IL4 rs2243248 was associated with higher degrees of fatigue, pain, sleep disturbance, and depression (Illi et al., 2012). Another more recent study (Reyes-Gibby et al., 2013b) assessed whether a panel of immune-response genes may underlie the co-occurrence of fatigue, severe pain, and depressed mood in non-small-cell lung cancer patients during treatment. Among 55 SNPs in the 37 genes, the researchers found that interleukin IL8-T251A was the most relevant genetic factor for fatigue.

### 3.2.2.2. Other mechanisms:

Three studies focused on SNP associations in other non-inflammatory related gene pathways (Athanasoulia et al., 2012; Fernandez-de-las-Penas et al., 2012; Vallance et al., 2010). Vallance et al. (2010) explored three mechanisms (pharmacokinetics, serum albumin and pharmacogenetics) through which dexamethasone may cause debilitating fatigue and disrupt sleep in pediatric acute lymphoblastic leukemia (ALL) patients during treatment. They found AHSG C > G (Thr238Ser) exon 7 genotype (rs4918) and POLDIP3 (rs1771889) to be associated with sleep disturbance but not fatigue. Fernandez-de-las-Penas et al. (2012) examined the influence of COMT Val158Met genotypes on cancer-related fatigue in breast cancer survivors; their results suggested that breast cancer survivors carrying the Met/Met genotype reported higher levels of fatigue.
Since 2012, the number of SNPs under investigation increased substantially. After examining 470 SNPs in 56 genes of three biologic pathways in 1299 patients with non-small-cell lung cancer, Sloan et al. (2012) found three SNPs in the MGMT gene (rs3858300, rs10741191 and rs3852507) in DNA repair pathway to be associated with overall QOL. Two SNPs (rs2287396 [GSTZ1] and rs9524885 [ABCC4]) from the glutathione metabolic pathway were associated with fatigue.

3.3. Other disease-related fatigue

3.3.1. Overview—Eighteen articles on other disease-related fatigue were found in our systematic review. The studies were published from 2003 to 2015, including six case-control studies (Bahadir et al., 2013; Helbig et al., 2003; McLaren et al., 2008; Piraino et al., 2012; Utge et al., 2010), five cohort studies (Allen et al., 2008; Bull et al., 2009; Lotrich et al., 2010; Scotet et al., 2005; Udina et al., 2013), three cross-sectional studies (Maluchenko et al., 2009; Ragnarsson et al., 2014; Vazquez-Rey et al., 2005), two longitudinal studies (Lee et al., 2014; Sundstrom et al., 2007) and two clinical trials (Becker et al., 2015; van der Deure et al., 2008). Sample sizes ranged from 33 to 31,192. The methods for assessing or diagnosing fatigue varied widely, including LFS, FIS, FAS, SF-11, SF-36, MFI-20, Chalder Fatigue Questionnaire, Beck Depression Inventory-II, VAS, SPHERE and PSC. Table 3 shows the details of the articles reviewed on other disease-related fatigue. The overall quality of the studies was moderately low, with a mean of 7.0. The main reasons for the lower scores were relatively small sample sizes, not mentioning genotyping blinding method, and insufficient description of confounders.

3.3.2. Mechanisms—The genes under investigations from these studies can be grouped into 3 categories: neurotransmitter systems and HPA axis (five studies) (Bahadir et al., 2013; Bull et al., 2009; Maluchenko et al., 2009; Ragnarsson et al., 2014; Utge et al., 2010), inflammation (six studies) (Becker et al., 2015; Helbig et al., 2003; Lee et al., 2014; Lotrich et al., 2010; Piraino et al., 2012; Udina et al., 2013) and other mechanisms (seven studies) (Allen et al., 2008; Dlugos et al., 2010; McLaren et al., 2008; Scotet et al., 2005; Sundstrom et al., 2007; van der Deure et al., 2008; Vazquez-Rey et al., 2005).

3.3.2.1. Neurotransmitter system and HPA axis: Similar to chronic fatigue syndrome, disease-related fatigue was found to be highly associated with alterations in the serotonergic system and HPA axis. One study found 5-HTT was associated with central fatigue (a form of fatigue linked to the central nervous system) among selected college students, and this association differed by gender (Maluchenko et al., 2009). Among migraine patients, the genotype frequency of methylene tetrahydrofolate reductase (MTHFR) gene, which is involved in the conversion of the active form of the vitamin folate to 5-HT, C677T was found to be higher in patients suffering from fatigue, compression, allodynia, and sleeplessness compared to controls (Bahadir et al., 2013). However, in patients undergoing pegylated IFN-α and ribavirin treatment for chronic hepatitis C infection, 5-HTT was not associated with symptoms of fatigue (p = 0.5) (Bull et al., 2009). Furthermore, a study of patients with Cushing’s syndrome found that the Bcl1 polymorphism (rs41423247) in NR3C1 was associated with fatigue (Ragnarsson et al., 2014). In a study by Smith and colleagues, unexplained chronic fatigue was found to be associated with neurotransmitter
related genes including polymorphisms in the catabolic enzymes, monoamine oxidase A and B (MAOA, MAOB) that break down monoaminergic neurotransmitters including serotonin, and four polymorphisms involved in HPA axis function (NR3C1-rs1866388, rs852977, rs258750, and POMC) (Smith et al., 2006).

3.3.2.2. Inflammation: In patients with post-Q fever fatigue syndrome (QFS), variants in HLA-DR-11, NRAMP, and IFNγ were associated with fatigue compared to controls (Helbig et al., 2003). Similar results were found in a study on acute sickness responses to infection, showing that IFNγ (rs2430561) was associated with increased fatigue (Piraino et al., 2012). In a study on side effects of IFN-α treatment, the only association observed was that IL-6 rs1800795 was associated with fatigue at baseline (Udina et al., 2013). Furthermore, a study on hepatitis C patients treated with IFN-α showed that IFN-α rs1800629 was associated with fatigue during treatment (Lotrich et al., 2010). In patients with HIV/AIDS, SNPs in select cytokine genes (IL1B rs1071676 and rs1143627, IL4 rs2243274, and TNFA rs1800683 and rs1041981) were related to fatigue (Lee et al., 2014). Moreover, in patients with ischemic stroke, IL1RN rs4251961 was associated with self-reported fatigue, and TLR4 rs4986790 and rs4986791 were associated with lower levels of fatigue (Becker et al., 2015). In patients with pegylated IFN-α and ribavirin treatment for chronic hepatitis C virus, IL-6 (rs1800795) was not associated with symptoms of fatigue (Bull et al., 2009).

3.3.2.3. Other mechanisms: Various other genetic linkages have been investigated in association with fatigue. Among patients with hemochromatosis, or iron-overload-related disease, the prevalence of C282Y homozygotes in the human hemochromatosis (HFE) allele was investigated in three studies (Allen et al., 2008; McLaren et al., 2008; Scotet et al., 2005). HFE regulates iron uptake by controlling the relationship between transferrin and the transferrin receptor (Gallego et al., 2015). All three studies observed significant associations between C282Y and fatigue. In a study on patients presenting with angina and normal coronary arteriograms (ANCA), a polymorphism of the human angiotensin-converting enzyme (ACE) gene was associated with fatigue scores (Vazquez-Rey et al., 2005). Among patients with mild traumatic brain injury, Apolipoprotein E (APOE) genotype was related to post-injury fatigue (Sundstrom et al., 2007). Furthermore, in a study of patients with primary autoimmune hypothyroidism, both the OATP1C1-intron3C > T and the OATP1C1-C3035T polymorphisms were associated with symptoms of fatigue and depression (van der Deure et al., 2008). In a study (Norheim et al., 2014) that aimed to identify SNP variants in primary Sjogren’s syndrome (pSS) patients with high and low chronic fatigue, variants associated with the Rho-dependent signaling pathway (rs3786654 and rs10416904 of protein kinase N1) and cell membrane transport proteins (rs10276819 of solute carrier family 25, member 40 or SLC25A40) were associated with fatigue.

4. Discussion

The goal of this systematic review was to determine patterns of associations between pathway-based genetic polymorphisms and fatigue (CFS, CRF and other disease-related fatigue), both individually and collectively. We found that functional genetic variations (100% of the SNPs investigated in the association studies were functional) in the pathways of neurotransmitter regulation, HPA axis function, and immune-mediated inflammation.

Brain Behav Immun. Author manuscript; available in PMC 2018 May 11.
appear to play important roles in the etiologies of CFS, CRF and other disease-related fatigue. This review provides empirical support for the association between functional polymorphisms in TNF-α, IL1b, IL4 and IL6 genes and elevated fatigue for all three subgroups of fatigue. We also found CFS shared a series of polymorphisms in HLA, IFN-γ, 5-HT and NR3C1 genes with other disease-related fatigue, however these SNPs (excluding IFN-γ) were not found to be adequately investigated in CRF.

The reviewed studies demonstrate that select neurotransmitter- and HPA axis-related genes may play important roles in both chronic fatigue syndrome and other disease-related fatigue. Specifically, polymorphisms in 5-HT, NR3C1, POMC, MAOA, MAOB, TPH2, COMT, GRIK2 and NPAS2 were all found to be associated with fatigue. 5-HT, a monoamine neurotransmitter known to regulate mood, appetite, and sleep, acts via interactions with 5-HT receptors, and fatigue and mood disorders may be regulated by altering the expression of these receptors (Couch et al., 2015). The glucocorticoid receptor NR3C1 mediates feedback within the HPA axis and influences concentrations of the glucocorticoid cortisol, which is known to impact metabolism, the immune system, and the brain as well as stress-related behaviors (Bao et al., 2008). As both low and high levels of circulating cortisol are related to CFS, HPA axis-related genes may affect CFS (Cleare, 2004). As discussed in our review, a variety of neurotransmitter and HPA axis-related genes, including POMC, MAOA, MAOB, and TPH2, were associated with CFS and other disease-related fatigue. Due to the fact that these polymorphisms have not been fully investigated in CRF, it is difficult to know the extent to which specific neurotransmitters may be involved. Future studies are necessary to elucidate the association between neurotransmitter and HPA-axis-related genes and CRF.

The reviewed articles reveal that the development of fatigue is influenced by immune dysregulation, where specific functional SNPs and genotypes of TNFa, IL1b, IL4, and IL-6 contribute to worsening or persistent fatigue (Saligan et al., 2015). Cytokine gene polymorphisms can significantly influence cytokine production levels. These findings are consistent with previous studies that have demonstrated associations between peripheral blood cytokine concentrations and fatigue occurrence or severity. A quantitative review (Schubert et al., 2007) suggested a positive correlation between fatigue and circulating concentrations of inflammatory markers. More importantly, genetic polymorphisms in these pathways may indicate a host predisposition to fatigue (Carlo-Stella et al., 2006). Among the cytokine SNPs investigated, GG genotypes of TNFa-308 was the only polymorphism significantly associated with all three subgroups of fatigue. TNFα is a pro-inflammatory cytokine involved in the regulation of a wide range of biological processes. These findings support the hypothesis that a TNF-α gene variation may be associated with differences in symptom frequency and severity of fatigue. This hypothesis was based on findings from clinical and experimental studies in both humans and animals suggesting that tumor and/or disease treatments can trigger increased \textit{in vivo} concentrations of TNF-α, which can further influence fatigue via cytokine regulation of CNS function (Aouizerat et al., 2009; Dantzer et al., 2008). Preliminary evidence also suggests that the SNPs rs16944 in IL1b and rs1800795 in IL-6 are associated with CRF during and after treatment (Bower et al., 2013; Collado-Hidalgo et al., 2008; Dhruva et al., 2015). Of note, these SNPs were not studied in CFS and other disease-related fatigue. Current studies also suggest that certain SNPs in IL1b, IL1RN, IL4 are associated with HIV and post-stroke related fatigue symptoms (Becker et al., 2015;
In addition, HLA-DR genes/gene products have been shown to play an immune-regulatory role in resistance or susceptibility to other infective agents. Relevant in this regard, *HLA-DR* polymorphisms have been related to other disease-related fatigue, such as in chronic Q fever (Helbig et al., 2003).

In addition to the neurotransmitter, HPA axis, and immune mechanisms discussed above, genes related to other mechanisms associated with CFS, CRF and other disease-related fatigue include *HFE C282Y*, *DCP1, ACE, APOE, OATP1C1, AHSG*, and *POLDIP3*. Several studies suggest that the polymorphism *HFE C282Y* may be associated with fatigue among Hereditary Hemochromatosis (HH) patients (Allen et al., 2008; McLaren et al., 2008; Scotet et al., 2005). Hereditary Hemochromatosis is a hereditary disease, known as iron overload, characterized by dysregulated iron absorption resulting in total body iron overload (Siezenga et al., 2004). It is known that the mutation of C282Y in the *HFE* gene is very common in patients with HH (Feder et al., 1996) and one of the most common clinical manifestations of HH is fatigue (Gasser et al., 2014). However, more work needs to be done to confirm the association between *HFE C282Y* and fatigue.

### 4.1. Limitations and future directions

We are limited in our ability to draw strong conclusions from the above discussed work due to limitations in the individual studies and general gaps of knowledge in our understanding of fatigue.

The first caveat to the discussed is that sample sizes for all the studies included in this review were relatively small. Across a total of the 50 articles, only seven (14%) have a sample size larger than 500. Additional studies with larger sample sizes are needed to ensure statistical power, especially considering that individual SNPs are likely only weakly associated with risk. With larger samples, more subgroup (stratification) analyses can also be conducted to further explore fatigue and health disparities across age, race, gender, and other groups.

The second caveat of the discussed work is that many of the studies lack an accurate case-definition, especially for CRF and other disease-related fatigue. For example, of the 50 studies described, only 20 conceptually defined fatigue. It may be that incongruities between studies in the described associations between fatigue and genetic polymorphisms are related to alternate definitions of fatigue, as well as varied requisite duration of symptoms (Saligan and Kim, 2012). Moreover, unlike CFS, clear definitions of fatigue with respect to duration and severity for cancer-related and other disease-related fatigue are lacking in the current state of knowledge. In addition, because most of the studies on CRF and other disease-related fatigue did not include a control group (i.e. lacking a cancer diagnosis or a disease history), we cannot determine whether the association between these polymorphisms and fatigue was specific to disease diagnosis and/or treatment (Collado-Hidalgo et al., 2008). Fatigue may also be applicable to individuals in the general population that experience symptoms as a result for example of stressful circumstances (Aouizerat et al., 2009). Finally, because of differences in the study designs (e.g. case-control or not), the results of this review should be interpreted with caution. For instance, studies using case-control designs that categorized participants as fatigued or not may generate biased effect estimates of SNPs.
fatigue association (disease misclassification bias) compared to studies that used severity of fatigue as a continuous variable as the primary outcome.

The third caveat is that, only 28% of the studies used a longitudinal design to examine the associations between genetic variations and fatigue. More longitudinal studies are necessary to assess the roles of disease progression and treatment in the experience of fatigue across groups of patients (Saligan and Kim, 2012). It is possible that other genetic associations with fatigue will emerge if the same analyses are conducted at different points in the patient’s disease or treatment, as classification of disease severity can change over time (Dodd et al., 2011).

Fourth, most of these studies used a candidate gene approach (all genes and SNPs were selected based on existing empirical literature and were thus hypothesis-driven), and therefore, there may be some influential polymorphisms that were not identified. It is notable that no genome-wide studies (GWAS) were found, thus there is a reasonable likelihood of biased findings from these 50 articles. Additionally, there was not a uniform statistical model used across the cited studies to assess SNPs-fatigue associations, and thus our original plan for a meta-analysis was impeded. Moreover, the use of statistical methods to address multiple comparisons across studies was limited.

Finally, despite all the limitation identified above, our review had three additional limitations. First, we may have missed studies that are ongoing but not yet published. Second, although we searched among four public databases, some relevant studies might have been found using other databases or different key words. Third, we could not conduct any statistical analysis, as there was no uniform genetic statistical model across the studies, and no information outlining the distribution of each genotype or allele that would allow us to assess/calculate the SNPs-fatigue association.

4.2. Strengths

Selection bias is a common concern in observational studies when subject participation depends jointly on exposure and disease status. However, the assessment of polymorphism prevalence is not subject to selection bias under the assumption that genotype does not influence subject participation that is dependent upon exposure and disease status as outlined by Morimoto and colleagues (Morimoto et al., 2003). This is a strength of these SNPs-fatigue association studies. In addition, more than half of these studies collected information on major covariates, thereby decreasing unmeasured confounding issues.

5. Conclusion

We found several potentially important associations of SNPs related to neurotransmitter systems, the HPA axis, and immune-mediated inflammation with fatigue, including CFS, CRF, and other disease-related fatigue. Our review suggests a major role for cytokine SNPs in all the three subgroups of fatigue. Additionally, the review supports the continued use of genetic and epigenetic perspectives in assessing the role neurotransmitters play in persistent fatigue among cancer survivors. We consider that new knowledge gained from these studies could help CFS, cancer, and other disease-affected patients and survivors, their healthcare
providers, and their caregivers by identifying specific genes of risk for fatigue, targeting subgroups of people who would most greatly benefit from supportive management of symptoms, as well as identifying pathways and mechanisms that might serve as targets for the development of cognitive behavioral interventions and novel medical therapies.
