Abstract

Spatial epidemiology has benefited greatly from advances in GIS technology, which permits extensive study of associations between various health responses and a wide array of socio-economic and environmental factors. However, many spatial epidemiological data sets have missing values for a substantial proportion of spatial variables, such as the census tract of residence of study participants. The standard approach is to discard these observations and analyze only complete observations. In this paper, we propose a new hierarchical Bayesian spatial model to handle missing observation locations. Our model utilizes all available information to learn about the missing locations, and propagates uncertainty about the missing locations throughout the model. We show via a simulation study that this method can lead to more efficient epidemiological analysis. The method is applied to a study of the relationship between fine particulate matter and birth outcomes in southeast Georgia, where we find smaller posterior variance for most parameters using our missing data model compared to the standard complete case model.

Keywords

Bayesian hierarchical model; conditionally autoregressive prior; data imputation; geographic information system; missing data

1 Introduction

Spatial epidemiology has benefited greatly from advances in GIS technology. GIS facilitates the study of associations between various health responses and a wide array of socio-economic and environmental factors. Despite improvements in data collection methods and GIS technology (Henry and Boscoe, 2008; Goldberg et al., 2008), missing data remain prevalent in spatial health data sets. In this paper, we specifically address the problem of study participants with uncertain residential locations.

This work is motivated by an analysis of the effects of fine particulate matter on preterm birth and low birth weight in southern Georgia. Figure 1 shows the 24 counties in the study domain, as well as the 177 census tracts in these mostly rural counties. While the majority of air pollution and health studies have been conducted in urban communities, there is a
growing interest to examine the effects of air pollution in rural communities. This is because rural communities often have a different susceptible population composition and are exposed to a different pollution mixture. In our data set, several predictors are known at the census tract level, including the variable of interest, fine particulate matter exposure, and the tract’s median income. The county of residence is known for all mothers, however, for 9.7% of the mothers in the study the census tract of residence is unknown (ranging by county from 2.7% to 57.1%). This uncertainty in the spatial location poses challenges in the health model, as it is not clear how to assign exposure to these mothers, or how to model variability in risk across tracts. The ability to utilize health data with uncertain residential location is particularly important in this setting because missing geocodes are most prevalent in rural regions, which have considerably smaller sample size compared to urban communities.

There is an extensive literature on missing data methodology, for example, Little and Rubin (2002) and Enders (2010). However, relatively few missing data methods are available that are specifically tailored for spatial data. Recently, methods for preferential sampling have been developed for cases where the locations of the observations are selected in a way that depends on spatial distribution of the response (Diggle et al., 2010; Pati et al., 2012). In models for these data, the locations are modeled jointly with the response. Although the spatial locations are modeled statistically, unlike our application the data sets considered in preferential sampling do not have missing values. In similar work, Reich and Bandyopadhyay (2010) model spatial data with predefined measurement locations, but with missing responses. In this approach, the location of missing responses are allowed to depend on the true value of the spatial process being measured. The situation addressed here differs from Reich and Bandyopadhyay (2010) in that the location of the observations is missing, but not the response. Most similar to our method is Cressie and Kornak (2003), who consider the case of a continuous spatial domain and discuss the effects of adjusting for measurement error in the sampling locations in the usual geostatical/Kriging setup. Our case is different in that we are dealing with areal data, and thus the missing locations are restricted to a finite set of indices, and we use covariates to inform about the missing data process.

In this paper, we propose a hierarchical Bayesian approach that accounts for uncertainty in the residential location of the study participants. We treat the missing locations as unknown random variables in the Bayesian model. By modeling these data hierarchically, we exploit all available information to inform about the missing locations, including the mother’s characteristics (e.g., race and martial status), census information (e.g., the percent married and racial composition of the census tracts), and the proportion of missing data in each census tract. By modeling the data using Bayesian methods, uncertainty about the missing locations is naturally propagated throughout the model, including the posteriors of the parameter relating fine particulate matter with the health response, which is the primary interest. The proposed approach also has the advantage of being a relatively straight-forward addition to standard computational algorithms used for Bayesian spatial epidemiology models. In particular, it can be implemented using the popular software OpenBUGS.

The remainder of the paper proceeds as follows. Section 2 describes the motivating data. The statistical model and corresponding computational details are given in Sections 3
through 5. In Section 6, we conduct a simulation study to illustrate the benefits of the proposed approach compared to the standard method. The method is applied to Georgia birth data in Section 7. Section 8 concludes.

2 Description of the Georgia birth data

Birth record data were obtained from the Office of Health Indicators for Planning, Georgia Division of Public Health. The study region consists of 24 counties (177 census tracts) located in southeastern Georgia (Figure 1). We considered only singleton births without structural birth defects conceived from the period January 1, 2002 to December 31, 2005. Gestational age was defined as the number of completed weeks between the reported date of last menstrual period and the date of birth. We removed records with birth weight less than 400g and records with gestational age less than 26 weeks or greater than 44 weeks. We restricted the analysis to non-Hispanic white and non-Hispanic black mothers between the age of 15 and 44. The data are summarized in Table 1.

Daily ambient concentrations of fine particulate matter (PM$_{2.5}$) were obtained from the Statistically Fused Air Quality (McMillan et al., 2009) database (FSD) available at the EPA website, http://www.epa.gov/heasd/sources/projects/CDC/index.html. The FSD database contains predicted daily PM$_{2.5}$ concentrations over contiguous 12km by 12km grid cells. The predictions are based on a Bayesian space-time hierarchical model that combines (1) observed PM$_{2.5}$ levels from the monitoring network; and (2) deterministic outputs from the Models-3/Community Multiscale Air Quality model. To account for spatial misalignment between the grid cells and census tract boundaries, we first calculated the proportion of the tract area that fall within each FSD grid cell. Then daily tract-level values were obtained by taking a weighted average.

The following tract-level population statistics were obtained from Census 2000 for females between the age of 15 to 44: total population count, proportion of race black, and the mean and standard deviation of the age distribution. The median personal income in 1999 and the proportion who were married were also obtained for females, without the age restriction, due to limited census data.

3 Hierarchical model for missing spatial locations

Let $Y_i$ be the binary indicator of low birth weight or preterm birth for birth $i = 1, \ldots, n$, and $s_i \in \{1, \ldots, N\}$ be the index of the residential region (e.g., census tract) for observation $i$. We use the binary regression model

$$g[P(Y_i = 1)] = \alpha(s_i) + X_i^T \gamma + W(s_i)^T \omega + Z_i(s_i)^T \beta,$$

where $g$ is a link function (e.g., logit or probit), $\alpha = [\alpha(1), \ldots, \alpha(N)]^T$ are spatial random effects to control for unmeasured spatial baseline risks and $\gamma = (\gamma_1, \ldots, \gamma_p)^T$, $\omega = (\omega_1, \ldots, \omega_w)^T$, and $\beta = (\beta_1, \ldots, \beta_q)^T$ are fixed effects. We separate the predictors into three types: $X_i$ are descriptions of the $i^{th}$ birth and are known even in the absence of $s_i$ (e.g., the mother’s age or education attainment), $W(s_i)$ are descriptions of the mother’s residential region (e.g.,
the tract’s median income) and are the same for all mothers in region $s_i$, and $Z_i(s_i)$ are covariates that depend on the mother’s region and vary for mothers in region $s_i$ (e.g., the average PM$_{2.5}$ concentration in region $s_i$ over mother $i$’s first trimester).

Our focus is to develop a statistical model for the case where a significant proportion of the residential locations are missing. Let $\delta_i$ be the binary indicator of a missing value. For the majority of observations, GIS calculates $s_i$ accurately and thus $\delta_i = 0$. For some observations, GIS is unable to specify $s_i$ and thus $\delta_i = 1$. Fortunately, in most such cases, we are able to place $s_i$ into a subset of indices $S_i \subset \{1, \ldots, N\}$, e.g., $S_i$ may be the indices of the census tracts within a county if the mother’s residential county can be obtained directly from the birth certificate or by geocoding using ZIP code. Clearly this complicates the spatial model, as it is unclear how to assign these observations a spatial random effect. This uncertainty also affects the regression portion of the model, since some of the predictors depend on $s_i$.

We account for uncertainty in the residential region using Bayesian modeling. The spatial index $s_i$ is treated as an unknown parameter in the hierarchical model. To exploit all available information that can be used to impute the missing locations, we specify the joint distribution of all data for observation $i$, $[Y_i, \delta_i, X_i, W, Z_i, s_i]$. To specify the model, without loss of generality, we define the joint distribution as the product of three conditional distributions,

$$
[Y_i, \delta_i, X_i, Z_i, s_i] = [Y_i|\delta_i, X_i, W, Z_i, s_i] \cdot [X_i|W, Z_i, s_i] \cdot [W, Z_i|s_i, s_i]. \quad (2)
$$

As is often the case in missing data modeling, assumptions are required about the missing data mechanism. A key assumption in our analysis is that given the spatial location and the predictors, the birth outcome is independent of the missing data indicator, i.e.,

$$
[Y_i, \delta_i|X_i, W, Z_i, s_i] = [Y_i|X_i, W, Z_i, s_i] \cdot [\delta_i|X_i, W, Z_i, s_i]. \quad (3)
$$

This seems reasonable in our setting because many GIS errors are caused by unmatched addresses in geocoding, for example, due to missing street numbers, and many variables known to be associated with coding errors (Kravets and Hadden, 2007) are provided by the birth records and included in $X_i$.

The models for the three conditional distributions in (2) are described below. The model for $Y_i|X_i, W, Z_i, s_i$ is given by (1). A flexible model for the missing data mechanism $[\delta_i|X_i, W, Z_i, s_i]$ is

$$
g[\text{P}(\delta_i = 1|X_i, W, Z_i, s_i)] = a(s_i) + X_i^T b + W(s_i)^T c, \quad (4)
$$

where $a = [a(1), \ldots, a(N)]^T$ are spatial random effects and $b$ and $c$ are regression parameters. We exclude time-varying coefficients $Z_i$ from this model, since it seems unreasonable that GIS success rate depends on time and is correlated with covariates such as ambient air pollution.
In some cases there may be prior information about the GIS success rate in each region which could be incorporated in the prior for \( a \). However, considerable effort is required to assess GIS error rate, especially for a large study region (Strickland et al., 2007). In the absence of prior information, it will be difficult to estimate the spatial random effects \( a \). Therefore, to avoid identifiability issues, we omit these random effects from the model, giving

\[
g \left[ P(\delta_i = 1|X_i, W, s_i) = \mathbf{x}_i^T \mathbf{b} + \mathbf{w}(s_i)^T \mathbf{c} \right. \quad (5) \]

This probability depends on \( s_i \) through \( \mathbf{W}(s_i) \), and therefore helps impute the missing indices. Also, intuitively, the data provide information about \( c \) by comparing the proportion of missing tracts in each county with the average \( \mathbf{W} \) over census tracts in the county. For these reasons, we select (5) as the missing data model in Section 7.

Next we describe the model for \([X_i, W, Z_i|s_i]\). The spatial covariate \( W \) is considered fixed and thus not modeled stochastically. For the GA data, there are no missing values or uncertainty in \( X \). However, it is still important to model their distribution given \( s_i \) because this provides information to impute missing census tracts. For example, a married mother is more likely to reside in a census tract with high proportion of married women. Therefore, a model for the proportion of married women in each census tract is needed so it can be combined with maternal information to help impute the missing census tract indicators. The predictors \( X_i \) are a mix of continuous and binary variables. If the \( j^{th} \) covariate, \( X_{ji} \), is continuous, we model \( X_{ji}|s_i \sim N[\mu_{ji}(s_i), \sigma_{ji}^2(s_i)] \); if \( X_{ji} \) is binary, we model \( P(X_{ji} = 1|s_i) = \mu_{ji}(s_i) \). In our data there is a single exposure (i.e., \( q = 1 \)), which is modeled as \( Z_i|s_i \sim N[\mu_{0i}(s_i), \sigma_{0i}^2(s_i)] \). If the exposure is known exactly in each census tract, then \( \sigma_{0i}^2(s_i) = 0 \) and \( \mu_{0i}(s_i) \) is the exposure for tract \( s_i \). In most air pollution studies, there is uncertainty in the exposure in each tract due to measurement error and incomplete sampling. Our approach to dealing with the uncertainty via priors for the \( \mu_{ji} \) and \( \sigma_{ji} \) is described in Section 4. It is also straightforward to treat \([X_i|s_i] \) as a multinomial distribution where each outcome represents a unique strata of \( X_i \). This is particularly useful when the prior is derived from census tables of several variables.

The third component of (2) is the prior of the residential location. We assume that 100\( \pi \)\% of the mother’s reside in region \( j \), with \( \sum_{j=1}^{N} \pi_j = 1 \). For partially observed locations restricted to \( s_i \in S_j \), the conditional prior is \( \text{Prob}(s_i = j|s_i \in S_j) = \pi_j/\sum_{k \in S_j} \pi_k \). The probabilities (\( \pi_1, \ldots, \pi_N \)) may be fixed based on census data, or given a prior to account for uncertainty in population density.

### 4 Prior distributions

Spatial random effects \( a \) in (1) are modeled using a conditionally autoregressive (“CAR”) model (Gelfand et al., 2010). The CAR model can be defined by its full conditional distributions,
\[ a_j | a_l \text{ for all } l \neq j \sim N\left(\mu + \frac{\rho}{m_j} \sum_{l \sim j} (a_l - \mu), \frac{\tau^2}{m_j}\right), \]  \hspace{1cm} (6)

where \( l \sim j \) indicates that regions \( l \) and \( j \) are adjacent, and \( m_j \) is the number of regions that are adjacent to region \( j \). The CAR prior has three parameters: \( \mu \) is the location, \( \tau^2 \) controls the variance, and \( \rho \in [0, 1] \) controls the degree of spatial dependence. Combining these full conditionals gives a multivariate normal joint distribution for \( \alpha \) with mean \( (\mu, \ldots, \mu)^T \) and covariance \( \tau^2(M - \rho D)^{-1} \), where \( M \) is the diagonal matrix with diagonal elements \( \{m_1, \ldots, m_N\} \), \( D \) is the adjacency matrix with \((j, l)\) element equal to \( I(j \sim l) \), and \( I \) is the binary indicator function. We denote this model \( \alpha \sim \text{CAR}(\mu, \tau, \rho) \).

For the data analysis in Section 7 we fix \( \rho = 1 \), which gives an improper intrinsic prior. For simulated data in Section 6 we fixed \( \rho = 0.9 \), since it is not possible to simulate data from the improper model with \( \rho = 1 \).

To complete the health model, we specify uninformative priors \( \mu_j \), \( \gamma_j \), \( \omega_j \), and \( \tau^{-2} \sim \text{Gamma}(0.1, 0.1) \). Similarly, the prior for the missing data parameters are \( b_j, c_j \sim N(0, 10^2) \).

The prior mean and variance of the air pollution exposure, \( \mu_0^i \) and \( \sigma_{0i} \), are provided by the FSD database described in Section 2. Although there is substantial variation in the daily exposures, the uncertainty is negligible after averaging over the entire first trimester and is therefore ignored by setting \( \sigma_0 = 0 \). The remaining values of \( \mu_j, \sigma_j, \pi_1, \ldots, \pi_N \) are fixed based on census data.

5 Computational details

Although it would be straightforward to implement in standard software such as OpenBUGS (Lunn et al., 2009), we perform MCMC sampling using R (R Development Core Team, 2010). We use a probit link \( g(x) = \Phi(x) \), where \( \Phi \) is the standard normal distribution function, for both the health model (1) and missing data model (5). Therefore, we introduce two auxiliary variables (Albert and Chib, 1993) for each subject, \( U_i \) and \( V_i \), with

\[
U_i \sim N(\alpha(s_i) + X^T \gamma + W(s_i)^T \omega + Z_i(s_i)^T \beta, 1) \hspace{1cm} (7)
\]

\[
V_i \sim N(X_i^T b + W(s_i)^T c, 1).
\]

The auxiliary variables relate to the responses by \( Y_i = I(U_i > 0) \) and \( \delta_i = I(V_i > 0) \).

Marginalizing over the auxiliary variables gives the desired probabilities in (1) and (5). After introducing these latent variables, all model parameters are conjugate, and therefore Gibbs sampling is used to generate samples from the posterior distribution.

Most of the full conditionals needed for Gibbs sampling follow from standard conjugacy relationships. A few parameters have non-standard full conditionals, which are specified below. The auxiliary variables have truncated normal full conditionals,
where the truncation region is \( \mathcal{D}(Y) = [0, \infty] \) if \( Y = 1 \) and \( \mathcal{D}(Y) = [-\infty, 0] \) if \( Y = 0 \).

Conditioned on the latent variables in (7) and assuming Gaussian priors, the full conditionals of \( \alpha, \gamma, \omega, \beta, b, \) and \( c \) follow from the usual normal/normal conjugacy relationship, and are thus omitted. The CAR variance \( \tau^2 \) has the standard gamma full conditional from normal/gamma conjugacy, and is omitted.

The final full conditional needed for the Gibbs sampler is for the missing location indices \( s_i \) for observations with \( \delta_i = 1 \). The full conditional is

\[
P(s_i = l | \text{rest}) = \frac{\eta_{il} \pi_{il} \prod_{l \in S_i}}{\sum_{k=1}^{N} \eta_{ik} \pi_{ik} \prod_{k \in S_i}}
\]

where

\[
\eta_{il} = \phi[U_i|\alpha(l) + \omega X_i^T + W(l)^T + Z_i(l)^T, 1] \\
\times \phi[V_i|X_i^T b + W(l)^T c, 1] \\
\times \prod_{j=1}^{p_1} \phi(X_{ij}|\mu_j(l), \sigma_j^2(l)) \\
\times \prod_{j=p_1+1}^{p} \mu_j(l) X_{ij} [1 - \mu_j(l)]^{1 - X_{ij}},
\]

the covariates are ordered so that the first \( p_1 \) covariates in \( X_i = (X_{i1}, ..., X_{ip}) \) are Gaussian and the remaining \( p - p_1 \) are binary, and \( \phi(y|m, s^2) \) is the \( N(m, s^2) \) density function.

For simulated data in Section 6 we generate 10,000 samples and discard the first 1,000 as burn-in. For the data analysis in Section 7 we generate 25,000 samples and discard the first 10,000 as burn-in. Convergence is monitored using trace plots of several representative parameters. We find that convergence is almost immediate for this model.

### 6 Simulation study

The data are simulated on a 6x6 regular grid of \( N = 36 \) census tracts. The tracts are partitioned into a 3x3 grid of counties as shown in Figure 2. Mothers’ census tracts are randomly assigned with equal probability. The county is known for each mother, but the census tract is missing with probability \( \pi \). In addition to air pollution exposure, there is a single \( (p = 1) \) binary predictor \( X_i \), which is known for all mothers. We vary the mean of the predictor by alternating columns in order to allow contrast in prevalence within a particular county. The predictor is generated as \( X_i|s_i \sim \text{Bernoulli}(\mu_X) \) for \( s_i \) in even numbered columns (Figure 2) and \( X_i|s_i \sim \text{Bernoulli}(1 - \mu_X) \) for \( s_i \) in odd numbered columns; we assume \( \mu_X \) is known to replicate known census information. For each mother, we randomly draw an exposure for each census tract, \( Z_i = [Z_{i1}, ..., Z_{iN}]^T \) iid \( \text{CAR}(0, 1, \rho_Z) \). For each simulated data set, the spatial random effects are drawn as \( a = [a(1), ..., a(N)]^T \sim \text{CAR}(\mu, \sigma^2, \rho) \). The responses are then generated as
Each simulated data set has \( n = 1000, \omega = 0.5, \mu = -1.0, \sigma = 0.1, \) and \( \rho = 0.9. \) For simplicity, we do not include spatial covariate \( W(s) \). For each simulated dataset we fit three models:

1. **Complete case (CC)**: discard all observations with a missing census tract
2. **Spatial uncertainty (SU)**: treat the missing census tracts as unknown parameters as described above
3. **Oracle (O)**: Use all observations as if we knew the missing census tracts

Model 1 is the simplest model which ignores uncertainty in the spatial locations by removing all problematic observations. Model 2 is our proposed approach. The final model cannot be fit to real data because it uses information that is not known to the analyst. This is included as a reference to gauge the effectiveness of the data imputation method.

We take as the base case for the simulation \( \pi = 0.2, \mu_X = 0.3, \beta = 0.5, \) and \( \rho_Z = 0.9. \) We then simulate data for several designs by varying these four factors. For each design we generate 200 datasets. Figure 3 plots root mean-squared error (RMSE) for \( \beta \), averaged over the simulated data set. We also computed the empirical coverage probabilities. They were at or above the nominal level for all models and simulation designs, and therefore we do not present them here.

As expected, the RMSE of the SU model is between the RMSE of the CC and O models for all settings. The improvement of the SU model compared to the usual CC model is highly dependent on the percent missing. The relative mean squared error of the SU to the CC model varies from \( (0.053/0.056)^2 = 0.941 \) with \( \pi = 0.1 \) to \( (0.053/0.069)^2 = 0.700 \) with \( \pi = 0.4. \) Increased variability in the mean of the covariate across census tracts (i.e., small \( \mu_X \)) improves the ability of the model to impute the missing census tracts. The average (over missing observation and data set) posterior probability on the correct tract increases from 0.26 with \( \mu_X = 0.5 \) to 0.43 with \( \mu_X = 0.05. \) Surprisingly, this does not translate into improved RMSE for \( \beta \), as the relative MSE is fairly constant for all \( \mu_X. \)

The SU model improves MSE for moderate signal with \( \beta = 0.25. \) However, for a very strong signal, the CC model is nearly as effective as the SU model. Finally, all methods give smaller MSE when the spatial dependence parameter for the air pollution exposure, \( \rho_Z \), increases. The spatial uncertainty model becomes increasingly efficient as the dependence increases. The relative mean squared error of the SU to the CC model varies from \( (0.058/0.066)^2 = 0.900 \) with \( \rho_Z = 0.80 \) to \( (0.038/0.043)^2 = 0.857 \) with \( \rho_Z = 0.99. \) This is because uncertainty in the census tract is less problematic when the census tracts have similar exposures.

### 7 Analysis of Georgia birth data

We examined the associations between exposure to ambient PM\(_{2.5}\) during the first trimester and the risk of low birth weight (less than 2500g) and preterm birth (less than 37 gestational week) separately via a spatial probit regression model. The total study population is 45,354
births and the raw prevalence was 11.3% for preterm birth and 6.9% for low birth weight. First trimester exposure was defined as the average daily PM$_{2.5}$ concentrations during the first 13 weeks of pregnancy. The model included the following confounders from the birth records: maternal age, indicator for race, indicator for infant sex, indicator for marital status (married or unmarried), and indicators for some college or higher and self-reported tobacco use during pregnancy. To control for unmeasured temporal confounders, the model also included: (1) indicators for the season of conception (spring: Mar–May, summer: Jun–Aug, autumn: Sept–Nov, winter: Dec–Feb); and (2) a smooth function of conception date modeled using natural cubic splines with 4 degrees of freedom. To control for spatial confounders, we included tract-level median personal income from Census 2000 and tract-specific spatial random intercepts via the CAR specification.

Table 2 summarizes the posteriors of the coefficients in the health and missing-tract models. Results are given for the spatial uncertainty (SU) model and complete case (CC) models defined in Section 6. Unmarried, black mothers without college education and with tobacco use have a higher risk of both preterm birth and low birth weight. Also, older mothers are at higher risk of preterm birth, and female babies are at higher risk of low birth weight. Based on these data, there is not a statistically significant relationship between PM$_{2.5}$ and either low birth weight or preterm birth.

The effect estimates are similar for both the SU and CC models. As expected, the posterior standard deviation is smaller for the most parameters under the SU model compared to the CC model. For the confounding predictors (Age – Education in Table 2) for preterm birth, the ratio of posterior variance for the CC compared to SU model ranges from $(0.0199/0.0192)^2 = 1.07$ for maternal race to $(0.0205/0.0191)^2 = 1.15$ for maternal marital status. For low birth weight, the ratio of posterior variances ranges from 1.00 for maternal age to $(0.0230/0.0215)^2 = 1.14$ for maternal education. These predictors are known for all observations, even those with missing census tracts, and so the SU model provides smaller variance due to the larger sample size. Curiously, the posterior standard deviation of the PM$_{2.5}$ effect for preterm birth is larger for the SU model than the CC model. This may be because the increased sample size for the SU model is offset by uncertainty in the PM$_{2.5}$ predictor.

The spatial random effect estimates in Figure 4 show considerable spatial variation, with significantly lower risk in the southeast portion of the spatial domain. Figure 4c plots the ratio of posterior variance from the CC model to the SU model. As with the fixed effects, the variance of the random effects is considerably smaller for the SU model.

There are several statistically significant predictors of the missing census tracts (Table 2). The results are nearly identical for preterm birth of low birth weight because the majority of information for these parameters comes from the regression of the missing data indicators and covariates, and these are the same for both health responses. White mothers without college education and in tracts with a low median income are more likely to have missing tract information. This provides information about the missing census tract, as does the mother’s covariate information. Figure 5 shows the posterior distribution of the missing tract index for each mother from Appling County. For all mothers, the probability for tract
13001950400 is small, since this tract has the smallest population (9% of the county’s population). The posterior probability for tract 13001950200 varies dramatically across mothers. The main driver of the probability is the mother’s race and marital status; of the 5 tracts in Appling County, this tract has the highest proportion of black residents (50.5%, no other tract exceeds 25%) and lowest proportion of married mothers (59.3%, all other tracts exceed 66%).

8 Discussion

In this paper we develop a hierarchical Bayesian model which incorporates uncertainty about the spatial location of the study participants. The method is straight-forward to implement in standard MCMC algorithms. We show via simulation that properly accounting for spatial uncertainty can lead to a substantial improvement in parameter estimation over the standard approach of discarding incomplete observations. The method is then applied to a study of the association between fine particulate matter and birth outcomes in Georgia. Although this analysis did not reveal a statistically significant association, accounting for spatial uncertainty reduced the posterior variance of the coefficients by as much as 15%. Our simulation study suggests that reductions in variance will be even larger for studies with more missing spatial information. For this large study where the complete case model already gives small standard errors, the credible sets that do or do not include zero are the same for both the complete case and spatial uncertainty model. However, more smaller studies, a 15% reduction in posterior variance could reveal new environmental factors relating to birth outcomes and lead to public health initiatives to improve birth outcomes.

As with many approaches to missing data problems, our analysis relies on strong assumptions. In particular, we are assuming that after accounting for covariate effects, accurate recording of the spatial location is independent of the response. This seems reasonable in our setting, but this assumption should be carefully scrutinized in future applications. Technically, the more complicated case of missing spatial locations depending on the response is still considered missing at random, and therefore it may be possible to include the response in the logistic regression model for the missing data indicator. This is an area of future work.

Figure 1.
Plot of the counties and census tracts in southern Georgia that constitute the study domain. The white areas indicate tracts with no births during the study period.
Figure 2.
Plot of the census tracts for the simulation study. Shading corresponds to the tract’s county.
Figure 3.
Simulation study results. Root mean square error (MSE) is plotted by the proportion of missing data ($\pi$), the mean of the covariate in the even numbered columns ($\mu_X$), the exposure effect $\beta$, and the spatial dependence parameter of the air pollution exposure ($\rho_z$). The Monte Carlo standard error is between 0.0028 and 0.0056 for all RMSE estimates.
Figure 4.
Summary of the spatial random effects $\alpha$ for the preterm birth analysis. Panels (a) and (b) plot the posterior mean and standard deviation of $\alpha$ for the SU model, and Panel (c) plots the ratio of posterior variance for the CC model relative to the SU model.
Figure 5.
Posterior distribution from the preterm birth analysis for the census tract index of each mother with a missing census tract from Appling County. Each set of 5 connected points represents the posterior distribution of $x_i$ for one mother.
