Abstract

As access to antiretroviral therapy increases, more HIV-infected patients in sub-Saharan Africa may desire fertility. We conducted a cross-sectional study of reproductive health knowledge, attitudes and practices to identify factors associated with desired fertility among women and men receiving care at two large public HIV clinics in Lilongwe, Malawi. Research assistants administered questionnaires to participants. We performed descriptive, bivariable and multivariable analysis of factors related to desired fertility and of factors related to contraceptive non-use among participants who did not desire fertility. One-third of participants desired future children. Having a partner who desired fertility and having lower parity were associated with desiring children among both genders. For women, believing that pregnancy was unhealthy was associated with decreased fertility desire. Fifty-five percent of women and 69% of men who did not want children in the future reported using contraception at last intercourse. Increasing age, lower parity, and making the decision to use contraception herself were associated with contraceptive non-use among women who did not desire fertility. Having discussed family planning with his partner was associated with contraceptive use among men who did not desire fertility. Knowledge of these factors can guide reproductive health counseling and service provision.
Introduction

As more people access antiretroviral therapy (ART) and live healthier and longer lives with human immunodeficiency virus (HIV) in sub-Saharan Africa, their desire for future pregnancy may be increasing [1–6]. HIV prevalence and ART use in Malawi is similar to much of sub-Saharan Africa: 10.6% of reproductive-aged adults are HIV-positive, and two-thirds of those eligible receive ART [7]. Among people living with HIV in sub-Saharan Africa, 35–75% desire children in the future [2,3,8–16]. In addition, people living with HIV, especially reproductive-age women on ART, tend to access health care more regularly than their peers [7]. HIV-positive women and men are a large and accessible group in need of reproductive life planning discussions [17]. These discussions would allow for targeted provision of contraception and medical guidance for achieving the healthiest possible pregnancy.

The desire for future childbearing among people living with HIV in sub-Saharan Africa has been associated with several sociodemographic, reproductive history, cultural, and HIV-related factors. Younger age, fewer living children, and having a partner who desires fertility have been consistently associated with increased desire to have future children among HIV-positive women and men in different populations [4,10–13,15,18–20]. To date, these factors associated with desired fertility have not been studied among women and men receiving care at large public HIV clinics in Malawi. This report identifies factors associated with desired fertility among HIV-positive women and men receiving care at large public HIV clinics in Lilongwe, Malawi’s capital. We also sought to describe contraceptive use and factors associated with not using contraception among participants who did not desire future fertility.

Materials and methods

Participants and procedures

We conducted a cross-sectional study of reproductive health knowledge, attitudes and practices among men and women receiving HIV-related care in Lilongwe, Malawi. The National Health Services Research Committee in Malawi and the institutional review boards at Emory University and University of North Carolina-Chapel Hill formally approved the study. All participants provided written informed consent prior to participation.

Women and men were recruited at two Lighthouse Trust clinics in Lilongwe, Malawi from September 26, 2013 to December 20, 2013. The Lighthouse Trust is a Centre of Excellence for Integrated HIV Prevention, Treatment and Care; and provided care for over 23,000 patients on ART and over 2,000 patients who were not yet clinically eligible for ART by December 2013. The Lighthouse Clinic is at Kamuzu Central Hospital, a tertiary referral hospital for the central region of Malawi, and the Martin Preuss Centre is at Bwaila Hospital falling under the Lilongwe District Hospital. Both are public clinics offering HIV treatment in the capital, and both began offering family planning services in 2010.

Study staff recruited patients by consecutive, non-random sampling from the clinic waiting areas and screened interested patients in private. We planned to enroll a convenience sample of 300 women and 300 men over a three-month period, based on budget and historical clinic attendance. Eligibility criteria included ages 18–45 years, fluency in Chichewa (the most commonly spoken local language), having a sexual partner within the past six months, having documented HIV-positive status, and receiving care at either Lighthouse clinic or Martin Preuss Centre. Research assistants administered the questionnaire in Chichewa. Male and female participants may have had partners who completed the study, but they were not interviewed as couples.
Survey and measures. The questionnaire included 160 questions for women and 130 for men (S1 and S2 Text). Research questions were developed through a combination of focus group discussions among female and male patients at the Lighthouse clinics and questions used in the Malawi 2010 Demographic and Health Survey [21]. All data from the questionnaires were double entered into a Microsoft Access 2007 (Microsoft, Redmond, WA, USA) database and validated using predetermined queries.

This report addresses one aspect of the study’s primary objective: desired fertility. This outcome was measured by a dichotomous “yes/no” answer the question: “Do you want or plan to have more children (at any time in the future)?” Potential variables related to fertility intention fell into six categories: sociodemographic, HIV-related, sexual characteristics and risk behaviors, reproductive history, communication and social pressure, and perceived risk of HIV in pregnancy. We also asked participants if they were currently using contraception and what method(s) of contraception they or their partners used at last intercourse.

Statistical analysis
We conducted descriptive, bivariable and multivariable analyses of variables potentially associated with the desire to have children in the future and contraceptive use among those who did not desire fertility. The descriptive analysis included participant characteristics and information on reported contraceptive use. We used Pearson’s $\chi^2$ and Fisher’s exact where appropriate to test bivariable associations. To describe unmet need for contraception in this group, we determined the frequency of current contraceptive use and reported types of contraception used by participants who did not desire fertility.

We planned separate regression models for each gender. The maximum number of variables included in each gender’s final model was limited to $m/10$, where $m$ is the smaller of the number of participants either desiring or not desiring future children. We first identified potential variable associated with desired fertility and contraceptive use in the literature and consensus clinical experience. From this list, we then eliminated any variables that likely duplicated the same construct, had a prevalence of $<10\%$ in one of the outcomes, or were less consistently associated with our outcome in the literature to reach the acceptable number of variables for each model. We ran Poisson regressions with robust standard errors to estimate unadjusted and adjusted prevalence ratios with 95% confidence intervals [22]. We used Stata (Release 13, StataCorp, College Station, TX, USA) for statistical analysis.

Results
Between September and December 2013, we screened 349 women and 274 men, and enrolled 308 (88%) and 254 (93%), respectively, for a total of 562 participants. Fewer men attended clinic during these 3 months than anticipated when planning our convenience sample. Of the 562 participants enrolled, 308 women and 250 men had data on our primary outcome and are included in this report (S1 Fig).

Thirty-four percent (105/308) of women and 28% (70/254) of men desired fertility (Table 1). Of participants who did not want future children, 101/204 (50%) women and 76/180 (42%) men desired fertility if they were counterfactually HIV negative (S1 Table).

Participant ages spanned the reproductive spectrum, and the mean ages of participants were 32 (SD 6.5) years for women and 37 (SD 5.4) years for men. The median time since being diagnosed with HIV was 4.0 years (IQR 2–7) for women and 3.5 (IQR 1–7) years for men. Most participants were taking ART, had at least one child, and did not feel pressured by family or community to have future children. Approximately one-fifth of participants had a child born with HIV. Forty-two percent (128/308) of women and 70% (68/250) of men had a

partner who desired fertility. A small proportion (14%, 44/302) of women were discouraged from childbearing by healthcare workers who knew their status, and more than half believed that a physician would support her decision to have future children. Although nearly all participants knew that HIV-positive women could give birth to HIV-negative infants, almost a third of women thought that using ART in pregnancy increased the risk of transmitting HIV to infants. Approximately two-thirds of women believed that pregnancy would be unhealthy for them.

In unadjusted analyses of women, lower parity, partner desiring fertility, and pressure from family or community were associated with increased fertility desire (Table 2). Older age, having a child born with HIV, and believing that pregnancy was unhealthy were associated with decreased fertility desire. In the multivariable analysis for women, lower parity and partner desiring fertility remained significantly associated with the desire for future pregnancy.

PR = prevalence ratio; aPR = adjusted prevalence ratio, CI = confidence interval; ART = antiretroviral therapy
$^a$ for each increasing year

https://doi.org/10.1371/journal.pone.0198798.t002
Believing pregnancy to be unhealthy for her also remained associated with decreased fertility desire. The strongest association was with partner desiring fertility (aPR 4.18, 95% CI 2.69–6.47).

In unadjusted analyses of men, younger age, having fewer children, partner desiring fertility, and pressure from family or community were associated with desired fertility (Table 2). In the multivariable analysis, partner desiring fertility and having fewer children were significantly associated with the desire for future pregnancy. Partner desire was again the strongest association (aPR 4.60, 95% CI. 2.94–7.18).

Among participants who did not desire fertility, 55% of women (111/202) and 69% of men (125/180) used contraception at last intercourse (Table 3). Only 18% (37/202) of women and 17% (24/180) of men used dual protection. Thirty-eight percent (42/202) of women used a highly effective contraceptive method (>99% effective, including implant, intrauterine contraception, tubal ligation or vasectomy), although 96% (198/202) used a method that was at least moderately effective (>90% effective, including highly effective methods as well as depot medroxyprogesterone acetate or oral contraceptives). Among men, 19% (35/180) used a highly effective method and 42% (75/180) used at least a moderately effective method.

In unadjusted analyses of women who did not desire fertility, lower parity and the woman deciding to use contraception on her own were associated with increased contraceptive non-use (Table 4). In the multivariate analysis, these factors as well as increasing age were associated with contraceptive non-use. The strongest association, which had a two-fold increase prevalence of contraceptive non-use, was having zero to one children compared with at least four children.

In unadjusted analyses of men who did not desire fertility, having disclosed his HIV status to his partner and having discussed fertility desires or family planning as a couple were associated with decreased contraceptive non-use (Table 4). In adjusted analysis, men who did not desire fertility but did discuss fertility desires or family planning with their partners had half the prevalence of contraceptive non-use as men who did not discuss these matters with their partners (aPR 0.49, 95% CI: 0.27–0.89).

Our study highlights several critical reproductive health issues that need to be addressed for people living with HIV. A third of participants in our study desired fertility and this was similar for both women and men. Lower parity and having a partner who desired fertility were associated with this desire for both genders. Women who thought that pregnancy was unhealthy were less likely to desire fertility. For those not desiring children, the unmet need for contraception among our study participants was high. These findings raise three important issues. First, addressing desired fertility among HIV-positive patients is important, especially because knowledge of safer conception and prevention of maternal-to-child transmission has been shown to be low in other low and middle income countries [23–25]. Second, clinical factors most easily accessible to providers, such as time since HIV diagnosis and ART use, may be less relevant to patients desiring fertility than reproductive history and personal relationships. Third, decreasing the unmet need for contraception is crucial.

Addressing reproductive life planning for people living with HIV is essential. A third of participants wanted to have children in the future, comparable to HIV-positive women and men in South Africa, Tanzania, Ethiopia, Uganda and among patient in private clinics in Malawi [2,4,8–15]. Asking people living with HIV about their intentions for pregnancy is necessary to improve maternal and child health outcomes, including optimizing other health conditions before conception.

In addition to improving health outcomes, reproductive life planning discussions for people living with HIV, dispelling misconceptions, would provide education on HIV prior to conception. Half the women not desiring fertility would want future children if they were not HIV-positive, and the belief that pregnancy was unhealthy was negatively associated with desiring fertility. More women might want to become pregnant if they were aware that pregnancy does not exacerbate maternal HIV disease if managed with ART and were counseled on how to best achieve a healthy pregnancy and reduce the risk of HIV transmission to their children. Most women in our study knew that HIV-positive women could have HIV-negative babies, but almost a third thought that ART increased the risk of maternal-to-child-transmission (MTCT).
of HIV. A woman’s belief in whether pregnancy is unhealthy for her may be similar to HIV
treatment optimism and concern about premature death, factors that have been related to the
desire for future pregnancies among HIV positive women in the region [26,27]. Responses
highlight the prevalence of community misconceptions regarding MTCT, HIV progression,
and their possible influence on family planning goals among people living with HIV. Previous
studies have outlined additional barriers to implementation of safer conception, including
health care provider (HCP) training and HCPs sharing positive experiences with elimination
of MTCT and safer conception methods during universal test-and-treat [28,29]. The ability
to act on improved knowledge is also crucial: access to ART/PMTCT services in Uganda
increased the desire for future childbearing among women [25]. Improved and ongoing
counseling alongside increased access to ART may allow couples to better understand their
options and act on their desires for family building.

Time since HIV was diagnosed and ART use—information accessible to clinical providers
and previously reported as associated with the desire to have children in other studies—were
not statistically significant in our adjusted model [2,4,30]. Our findings on ART use may have
been affected by the high prevalence of ART use in our population. Studies outside of Malawi
have shown mixed results for whether time since HIV diagnosis is related to desire for future
children [26,31]. Factors that influence desire for children among uninfected individuals may
similarly be influential among HIV-infected men and women.

Similar to other studies in Malawi and other sub-Saharan countries, we found that having
fewer children and partner’s desired fertility were associated with HIV-positive men and
women desiring fertility [2,4,10–13,19,20,32]. Interestingly, age—which is inconsistently
reported as associated with fertility intentions—was not associated with the desire for future
children in our study. It is likely that some correlation exists between age and parity, and parity
drives the association with desire for children more so than age. In addition, in other studies
that analyzed age as a continuous variable, the effect size was small and very similar to ours
[4,15,18].

The unmet need for contraception among participants who did not desire fertility in the
future was high. Among those using contraception, few used the most effective, longest-acting
methods. In particular, only two participants reported using the copper intrauterine device,
which is both extremely effective and safe for use for most HIV-infected women. Given
that many people living with HIV may want to have children in the future after counseling,
increased access to highly effective reversible methods is especially important. Our study clin-
ics offered the range of reversible methods listed in Table 3, and permanent methods could be
obtained at the public hospitals where clinics are located. Our findings may therefore not be
generalizable to clinics without integrated family planning. Although this study was unable to
assess barriers to contraceptive use, evaluation of national, local, and clinic-level barriers to
contraceptive access may help HIV clinics and providers remove specific barriers to providing
HIV-positive individuals effective and desired contraception.

Understanding factors related to contraceptive non-use among women and men who
do not desire fertility may help with addressing the unmet need for contraception. Among
women who did not desire fertility, increasing age and the woman making contraceptive deci-
sions by herself were counter-intuitively associated with contraceptive non-use. This may
reflect decreased perceived risk of fertility along with increased reproductive autonomy with
age. Among men who did not desire fertility, discussing family planning with his partner was
associated with contraceptive use. The positive association between discussing contraception
with male partners and contraceptive use has been demonstrated previously [33]. Future stud-
ies that directly ask this population about reasons for non-use would provide important infor-
mation to guide contraceptive counseling.
Our results are subject to limitations. Our questionnaire measured both fertility desire and planning together. We chose to focus on desired fertility as our outcome, but participants may have considered the planned intention in their answer. Our convenience sample might not have fully represented the population of patients at the clinics. We enrolled participants prior to changing guidelines regarding injectable contraception among women at high risk for HIV acquisition and studies that raised concern for interactions between certain ART and implant effectiveness [34–36]. Our study population was a mostly parous group of men and women in long-term partnerships who were receiving care at large public HIV clinics with affiliations to academic centers in Malawi and the United States. Our findings may therefore not be generalizable outside of this group. The homogeneity of our participants in regards to ART use, being in committed relationships, and disclosing their status to partners also limited our ability to study these factors previously found to be related to desired fertility [2,10,11,18,19,32]. However, the two clinics provide HIV management for a large portion of HIV-positive people in Malawi’s capital.

Conclusions
Our findings provide guidance for medical providers and community workers caring for HIV-positive people in Malawi. People living with HIV deserve a full discussion of reproductive life planning. Although the majority of HIV positive patients need access to contraception to meet their reproductive goals, many desire and achieve future childbearing. Knowledge of factors associated with the desire for pregnancy may help frame discussions with this population and address gaps in knowledge about safer conception and prevention of maternal-to-child transmission of HIV. Future studies that evaluate the best way to deliver reproductive life planning to this population are necessary.

Acknowledgments
The authors wish to thank Joanne Garrett for her statistical advice during analysis, and Gretchen Stuart and Bill Miller for comments on the manuscript. Finally, we are indebted to all study participants, who were willing to share personal information about their reproductive
lives and wishes, the study research assistants (Justin Milonde and Felix Mtunga), and the staff of the Lighthouse Trust Clinics for their assistance and support of the study.
