Introduction

Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease characterized by progressive upper and lower motor neuron degeneration [1]. Although motor cortex impairment is the hallmark feature of ALS, there is increasing evidence indicating the involvement of widespread extramotor brain areas [2–5]. Particularly, as a major relay station in the brain that modulates input from many cortical areas and a filter for sensory input [6], the involvement of the thalamus in ALS has been reported by a number of studies using diffusion MRI [7,8], MR spectroscopy [9], fMRI [10], CT perfusion [11], and PET [12,13].

The thalamus and cerebral cortex are connected via topographically organized white matter tracks with parallel pathways, linking distinct cortical areas to specific thalamic nuclei [14,15]. However, while numerous studies have reported thalamic abnormalities in ALS, it still remains unclear whether all thalamocortical networks are affected equally in ALS, or whether there is selective impairment.

Until recently, in vivo examination of individual thalamocortical networks has been challenging. Conventional fMRI requires multiple fine-tuned cognitive paradigms to reliably activate distinct cortical areas and their associated thalamic counterparts [16]. Fortunately, recent development of connectivity analysis with...
diffusion tensor imaging (DTI) has enabled us to approach this challenge with probabilistic tractography and connectivity-based segmentation [17–19]. In this analysis, it is possible to separate regions of differing specialization of the human cortex by utilizing underlying white matter pathways [20].

In this work, we used tractography-based thalamus parcellation to identify different thalamic subregions [19,21] and to further elucidate possible differentially affected thalamocortical networks in ALS. Based on existing knowledge about ALS, we hypothesized that motor-related thalamocortical connectivity would be affected in ALS.

Materials and Methods

Participants

Thirty-eight individuals (25 males/13 females) with a diagnosis of sporadic probable, or definite ALS, according to the revised El Escorial criteria [22], were recruited from the Department of Neurology at Southwest Hospital in Chongqing, China. Clinical status of the participants was assessed by the ALS Functional Rating Scale-Revised (ALSFRS-R) [23] within 12 h after the MRI scan. Disease duration was calculated from symptom onset to the scan date in months, and the rate of disease progression was defined as follows: (48 – ALSFRS-R score)/(disease duration) [24–26]. None of the patients included in this study received any specific treatment. Exclusion criteria were as follows: (1) family history of motor neuron diseases, (2) clinical diagnosis of frontotemporal dementia [27], (3) the presence of other major systemic, psychiatric, or neurological illnesses, and (4) cognitive impairment (score < 26), as determined by the Montreal Cognitive Assessment [28].

Thirty-five healthy controls (21 males/14 females) with no previous history of neurological or psychiatric diseases and with normal brain MRI scans were recruited from the local community. All the participants were right-handed according to the Edinburgh Inventory [29].

This study was approved by the Medical Research Ethics Committee of Southwest Hospital, and written informed consent was obtained from all the participants.

Data Acquisition

MRI data were obtained from a 3T scanner of Siemens Tim Trio (Siemens, Erlangen, Germany) with an eight-channel head coil. The DTI data were acquired in two identical scans using a single-shot, single refocusing spin-echo, echo-planar imaging sequence. Eighty subjects (32 males/48 females; aged: 22–36 years) from the HCP dataset of “WU-Minn” (The Washington University and University of Minnesota) were used in this study. The detailed imaging protocol could be found at https://www.humanconnectomeproject.org/documentation/Q1/imaging-protocols.html.

Data Preprocessing

Our DTI data were preprocessed using the FMRIB’s Diffusion Toolbox included in the FMRIB’s Software Library (FSL, http://www.fmrib.ox.ac.uk/fsl) [31,32]. The preprocessing steps for DTI data included correction of eddy current distortion, brain extraction, diffusion tensor fitting, and estimation of diffusion orientation distribution functions. DTI data of the independent HCP sample were obtained and preprocessed using HCP’s diffusion preprocessing pipeline [33,34].

Masks of Thalamus and Cerebral Cortex

The DTI-based fiber tracking involved 3D masks in both thalamus and cerebral cortex. The mask of the thalamus was extracted from the Harvard-Oxford subcortical structural atlas in the MNI space (http://fsl.fmrib.ox.ac.uk/fsl/fslwiki/Atlases) and voxels located in ventricles or white matter regions were removed (Figure 1A). In the cortex, seven masks were adopted from a previous study [19,35] in each hemisphere including bilateral (1) prefrontal cortex (PFC), (2) premotor cortex (PMC), (3) primary motor cortex (M1), (4) somatosensory cortex (SC), (5) parietal cortex (PC), (6) occipital cortex (OC), and (7) temporal cortex (TC).

Thalamus Parcellation Based on HCP Data

Probabilistic tractography was used to delineate white matter pathways from the thalamus to the cerebral cortex. The algorithm accommodated crossing fibers in each voxel [21] by sending 5000 tracks from each voxel in the thalamus to the seven ipsilateral cortical regions. As a result, a probabilistic map of connections for each of the seven cortical targets was generated. Then, thalamus voxels of each participant were classified based on their strongest cortical connectivity (winner-take-all) into seven subregions [19]. After transforming individual parcellations into the MNI space, the algorithm of “Simultaneous Truth and Performance Level” (STAPLE) was applied to fuse individual segmentations [36]. The STAPLE approach was used to combine manual tracings of the same subject from multiple raters and to estimate the hidden “ground truth” consensus from a probabilistic model.

After fusing segmentation results across individuals in the HCP sample, the merged result (Figure 1B) was transformed from the MNI space back into the individual diffusion space for subsequent analyses of different thalamocortical connections.
Thalamocortical Tractography in the Recruited Sample

Here, probabilistic tractography was performed between each thalamic subregion and its ipsilateral counterpart in the cortex. The thalamus and cortex regions mutually served as seed and target in two symmetric tractography runs so that the direction effect was removed. After 5000 samples sent from each seed voxel, the maps of streamline counts between each seed and target pair were normalized by the total number of samples (5000) multiplied with the voxel number in the seed mask and thresholded at 5, 10, and 25% [18]. These thresholded and binarized masks were further evaluated on across-subject reproducibility, and the most reproducible one was subsequently utilized as tract-based region-of-interests from which DTI measures (FA, axial diffusivity (AD, diffusion parallel to the axon fibers), radial diffusivity (RD, diffusivity perpendicular to the axonal fibers, and mean diffusivity (MD, a mean of all three eigenvalues of the diffusion tensor) were extracted for group comparison.

Reproducibility of Thresholded Track Pathways

The reproducibility of thresholded track pathways was defined by spatial overlap across individuals and quantified by the Overlap By Pairs (OBP) [37]. If a group includes m pairs of images, with m representing different subjects and A/B corresponding to the mask, the following formula can be obtained:

\[
OBP = \frac{\sum_m (A_m \cap B_m)}{\sum_m (A_m \cup B_m)}
\]

DTI Measures

DTI measures of FA, MD, AD, and RD were extracted from the 5% binarized (most reproducible, see results below) probability maps of structural connectivity. All DTI measures were compared between groups with independent (two) sample t-tests using MATLAB Release 2012b (The MathWorks, Inc., Natick, MA, USA).

Results

Demographic and Clinical Data

The demographic and clinical characteristics of the present sample are summarized in Table 1. All individuals with ALS exhibited clinical signs of upper and lower motor neuron involvement. Seven individuals with ALS were classified as “bulbar onset,” thirty as “limb onset,” and one as “both bulbar and limb onsets.”

Independent sample t-test for age and two samples Kolmogorov–Smirnov test for gender distribution were used to compare the patient and control group. The significant difference was determined by *P* < 0.05.

Figure 2 Spatial overlap rates of bilateral thalamocortical structural connectivity from each thalamic subregion to its corresponding cortex in patients and controls at the probabilistic thresholds of 5, 10, and 25%. Spatial overlap was highest at a threshold of 5%.

Figure 3 Probabilistic tractography maps between left/right thalamic subregions and ipsilateral specific cortex regions were presented at a threshold of 5% in patients with ALS and healthy controls.
The Smirnov test for gender were performed and showed nonsignificant group difference on both variables.

### Group Differences in Thalamocortical Connectivity

Connectivity-based thalamus parcellation in the HCP sample is shown in Figure 1B.

In Figure 2, measures of spatial overlap for binarized probability maps are compared at thresholds of 5, 10, and 25%. The across-subject overlap was highest at the threshold of 5%.

In Figure 3, probabilistic tractography maps are compared between groups at the threshold of 5% for the seven thalamocortical pathways.

Group comparisons of DTI measures (FA, MD, AD, and RD) of the seven thalamocortical connections at a threshold of 5% are detailed in Table 2 (the results at thresholds of 10 and 25% are shown in the Tables S1 and S2, respectively). At the threshold of 5%, FA values of the bilateral premotor (left thalamus-PMC, \( t = 3.05, P = 0.003 \); right thalamus-PMC, \( t = 2.52, P = 0.01 \)) and motor (left thalamus-M1, \( t = 2.34, P = 0.02 \); right thalamus-M1, \( t = 2.24, P = 0.03 \)) pathways were significantly decreased in the ALS group.

#### Imaging and Clinical Measures Correlation Analyses

To investigate potential correlations between the imaging metrics and clinical variables, Pearson’s correlations were calculated. As shown in Figure 4, significant negative correlations were noted between the FA of bilateral thalamocortical connections in premotor (left: \( P = 0.002 \); right: \( P = 0.03 \); Figure 4A) and motor (left: \( P = 0.004 \); right: \( P < 0.001 \); Figure 4B) pathways. There were no other significant associations between imaging findings and clinical data.

#### Discussion

In vivo neuroimaging [8,9,12,38] and postmortem neuropathological studies [3,39,40] have both confirmed thalamic involvement in ALS. Extending from these previous studies, the present study capitalized on tractography-based thalamus parcellation and probabilistic tractography to examine differential impairment of thalamocortical structural connectivity. We found that the structural connectivity of thalamocortical pathways associated with PMC and M1 was both impaired in ALS, while the other thalamocortical connections remained relatively intact. In addition, FA values

of the impaired thalamocortical structural connectivity were inversely correlated with the disease duration.

**Differential Vulnerability of Thalamocortical Structural Connectivity**

The present data suggest that the thalamocortical motor connectivity is prominently affected in ALS. Given the apparent motor disabilities in individuals with ALS, these findings are perhaps not surprising. However, previous neuroimaging studies have not directly examined potential selective impairment in different thalamocortical connections. Our results indicate that structural networks linking the cortex to the thalamus are differentially affected in ALS. This finding is consistent with the four-stage neuropathological model proposed by Braak et al. [41,42], which suggests that the involvement of the thalamus sequentially starts in the ventrolateral posterior thalamic nucleus, progresses to the ventral anterior thalamic nucleus and the mediodorsal thalamic nucleus, and eventually covers the whole thalamus. Correspondingly, cortical impairments progress from the primary motor cortex to the premotor cortex.

**Relationship of Neuroimaging and Clinical Measures**

We revealed strong inverse correlations between ALS duration and FA decrement in motor-related thalamocortical pathways. These findings may be valuable for assessing the progression of ALS and could be considered as an *in vivo* imaging biomarker [43]. They also suggest that further studies using more specific motor function evaluation may be helpful in screening whether motor dysfunction is related to distinct patterns of thalamocortical structural connectivity alterations.

**Limitation**

The main limitation of the current study is the lack of a detailed evaluation of the motor status in individuals with ALS, which prevented...
us from examining the association between imaging measures and clinical symptoms, weakening the interpretation of our results.
