### Abstract

The magnetic nanoparticle has emerged as a potential multifunctional clinical tool that can provide cancer cell detection by magnetic resonance imaging (MRI) contrast enhancement as well as targeted cancer cell therapy. A major barrier in the use of nanotechnology for brain tumor applications is the difficulty in delivering nanoparticles to intracranial tumors. Iron oxide nanoparticles (IONPs; 10 nm in core size) conjugated to a purified antibody that selectively binds to the epidermal growth factor receptor (EGFR) deletion mutant (EGFRvIII) present on human glioblastoma multiforme (GBM) cells, were used for therapeutic targeting and MRI contrast enhancement of experimental glioblastoma both *in vitro* and *in vivo* after convection-enhanced delivery (CED). A significant decrease in glioblastoma cell survival was observed after nanoparticle treatment and no toxicity was observed with treatment of human astrocytes ( $P < 0.001$ ). Lower EGFR phosphorylation was found in glioblastoma cells after EGFRvIIIAb-IONP treatment. Apoptosis was determined to be the mode of cell death after treatment of GBM cells and glioblastoma stem cell (GSC)-containing neurospheres with EGFRvIIIAb-IONPs. MRI-guided CED of EGFRvIIIAb-IONPs allowed for the initial distribution of magnetic nanoparticles within or adjacent to intracranial human xenograft tumors and continued dispersion days later. A significant increase in animal survival was found after CED of magnetic nanoparticles ( $P < 0.01$ ) in mice implanted with highly tumorigenic glioblastoma xenografts (U87ΔEGFRvIII). IONPs conjugated to an antibody specific to the EGFRvIII deletion mutant constitutively expressed by human glioblastoma tumors can provide selective MRI contrast enhancement of tumor cells and targeted therapy of infiltrative glioblastoma cells after CED.

### Keywords

Glioblastoma; Magnetic Nanoparticles; Convection-Enhanced Delivery; MRI; EGFR

## Introduction

Despite the use of conventional therapeutic modalities such as surgery, chemotherapy, and ionizing radiation (IR), the prognosis in patients with malignant gliomas remains poor (1). Virtually all glioblastoma multiforme (GBM) tumors, the most common malignant glioma, recur at the site of their initial treatment due to the presence of infiltrating cancer cells in the surrounding normal brain that resist therapy or go untreated. Infiltrating cancer cells include a subpopulation of glioblastoma stem cells (GSCs) shown to be integral to tumor development, perpetuation, and therapy resistance (2,3). Imaging and targeted therapy of infiltrating GBM cells within the normal brain remains limited.

The epidermal growth factor receptor variant III (EGFRvIII) is a tumor-specific mutation that is expressed in malignant gliomas and not in the normal brain. This mutation encodes a constitutively active tyrosine kinase that enhances tumorigenicity and accounts for radiation and chemotherapy resistance (4,5). The 801 base-pair in-frame deletion in the extracellular domain of the EGFR results in the fusion of normally distant EGFR gene and protein sequences (6,7). The 14 amino-acid fusion junction sequence has been chemically synthesized and used to create an anti-synthetic peptide antibody that is highly specific for the deletion mutant EGFR protein compared to the intact EGFR protein (8,9). Vaccination of the fusion junction peptide sequence has been shown to be efficacious immunotherapy in syngeneic murine models and in humans with two consecutive and one multi-institutional Phase II trials (10).

The magnetic nanoparticle has emerged as a potential multifunctional clinical tool that can provide cancer cell detection by magnetic resonance imaging (MRI) contrast enhancement as well as therapy by cancer cell targeted delivery of therapeutic agents (antibodies, drugs, and small molecule inhibitors) or by the local hyperthermia generated from absorbing energy from an alternating magnetic field. Iron oxide nanoparticles (IONPs) in the size range of 10–25 nm have unique magnetic properties, which generate significant transverse  $T_2$  relaxation time shortening and susceptibility effects resulting in strong  $T_2$  weighted contrast on MRI (11). IONPs can evade the immune system and target cancer cells for destruction while simultaneously providing MRI contrast. Most IONPs are biodegradable and considered to have low toxicity (12). IONPs have been used in the clinical setting with humans (13). Currently, various formulations of IONPs have been developed for drug delivery schemes (14), magnetic cell separation and cell targeting (15), magnetic resonance imaging (MRI) contrast enhancement (16,20), and hyperthermia treatment of cancer (17,21–23).

Cell specific imaging by nanotechnology for detection and treatment monitoring holds great promise for the therapy of various cancers including central nervous system tumors (24,25). However, a major barrier in the use of nanotechnology for brain tumor applications is the difficulty in delivering nanoparticles to intracranial tumors. Conventional systemic delivery is limited due to the nonspecific nanoparticle uptake by the reticulo-endothelial system (RES) and problems in penetrating the blood-brain barrier (BBB). Convection-enhanced delivery (CED) is a minimally invasive surgical procedure that provides fluid convection in the brain by a pressure gradient which bypasses the BBB. Therapeutic agents can be delivered into the brain by CED in high concentrations (26,27) without toxicity to normal tissue and organs commonly associated with systemic delivery. The use of CED can also allow for therapeutic targeting of infiltrating cancer cells, a major cause for brain tumor recurrence after surgery. We report the use of IONPs conjugated to an anti-synthetic peptide antibody (EGFRvIIIAb) specific to the deletion-mutant epidermal growth factor receptor for image-guided CED in a mouse glioma model. The EGFRvIIIAb-IONP complex can provide

MRI contrast enhancement of human glioblastoma cells *in vitro* and an antitumor effect both *in vitro* and *in vivo* after CED.

## Methods

### Animals, Cells, and EGFRvIII Antibody

The human glioblastoma cell line, U87MG, was obtained from the American Type Culture Collection (ATCC) within the last six months and maintained in standard culture conditions. The U87MG cell line was stably transfected with either a plasmid for over-expression of the deletion mutant EGFRvIII (U87 $\Delta$ EGFRvIII) or the wild-type (wt) EGFR (U87wtEGFR) and tested by Western blot analysis (Fig. S1). Neurospheres were harvested from patient GBM specimens (Patients #74, 1002, and 30) at the time of surgical resection and cultured using serum-free medium supplemented with growth factors. Patient tumor specimens were harvested with approval by the Emory University Institutional Review Board (Protocol #642-2005). Glioblastoma neurospheres were tested by Western blot analysis (Fig. S2) for the GSC stem cell marker, CD133 (Cell Signaling), EGFRvIII (GenScript Corp.), and wt EGFR (Cell Signaling). Over-expression of the deletion mutant EGFRvIII confers enhanced tumorigenicity in immunocompromised rodents (4). Six- to 7-week old athymic nude (nu/nu) mice were used, and all procedures were performed with approval by the Institutional Animal Care and Use Committee (IACUC) of Emory University. The IgG polyclonal EGFRvIII antibody (6 nm and 150 kD) was generated by GenScript Corp. (Piscataway, NJ) in rabbits and purified based on a prior publication (8). Briefly, the rabbit polyclonal EGFRvIIIAb represents an anti-synthetic peptide antibody that reacts to the fusion junction of the deletion mutant EGFRvIII receptor expressed in human glioblastoma tumors.

### IONP Bioconjugation

Briefly, activation of the carboxyl groups on the IONPs was performed for conjugation of the EGFRvIII antibody after addition of an Activation Buffer, ethyl dimethylaminopropyl carbodiimide (EDC), and sulfo-NHS. The EDC/NHS solution was mixed vigorously with the IONPs at 25 °C for 15 min. Excess EDC and sulfo-NHS were removed from the activated nanoparticles by three rounds of centrifugation (1,000g) and resuspension in PBS using Nanosep 10K MWCO OMEGA membrane (Pall Life Sciences). The IONPs with activated carboxyl groups were then reacted with the EGFRvIII antibody (50  $\mu$ l at 2 mg/ml) at 25 °C for 2 h, and the reaction mixture was stored at 4 °C overnight. Excess antibody was removed by three rounds of centrifugation and resuspension in PBS using 300K MWCO OMEGA membranes. Mobility shift in 1% agarose gel was visualized by staining with 0.25% Coomassie Brilliant Blue in 45% methanol, 10% acetic acid for 1 h, and destaining in 30% methanol, 10% acetic acid overnight (Fig. S3).

### Binding of IONPs to Glioblastoma cells

Glioblastoma cells (U87 $\Delta$ EGFRvIII) were seeded in triplicate in 60 mm flat-bottomed plates and incubated overnight at 37 °C. Confluent monolayers of cells ( $1 \times 10^6$ ) were incubated with the IONP or EGFRvIIIAb-IONP solution (0.15 mg/ml) for 1 or 2 hours for MRI experiments. Washing of cells was performed with 10% phosphate buffer solution (PBS) to remove the excess nanoparticle solution. Treated cells were collected after scraping and placed in 10 ml tubes containing warm 0.8% agarose solution. MRI measurements were made with a 3 T clinical capable scanner. The  $T_2$  relaxation times of cells treated with IONPs were measured using a multi-echo fast spin echo sequence with 32 TE values ranging from 6 ms to 180 ms and an interval of 6 ms. The  $T_2$  relaxation time was calculated by fitting the decay curve using the non-linear mono-exponential algorithm of  $M_{(TE)} = M_0 * \exp(-TE/T_2)$ . Please see Supplemental Methods for transmission electron microscopy (TEM) studies.

## Human Astrocyte and Glioblastoma Cell IONP Toxicity Studies

Human astrocytes were kindly provided by the Yong Laboratory at the University of Calgary, Alberta, Canada. The astrocytes were cultured based on a prior published protocol (28). Toxicity experiments were performed on human astrocytes seeded in triplicate on 48-well flat-bottomed plates ( $10^5$  astrocytes/well). Cells were treated with free IONPs (0.3 mg/ml) or control vehicle (serum-free medium) for 1 hour at 37 °C. Glioblastoma cells (U87MG and U87 $\Delta$ EGFRvIII) were seeded in triplicate in 48-well flat-bottomed plates (80,000 cells/well) and incubated overnight at 37 °C. Confluent monolayers of cells were washed with PBS and then incubated with control (PBS), IONPs (0.2 mg/ml), EGFRvIIIAb (0.2 mg/ml), or EGFRvIIIAb-IONPs (0.2 mg/ml) for 1 hour at 37 °C. Cells were then washed with PBS and the crystal violet cell viability assay was performed at 0, 1, and 3 days. Cells were stained with 100  $\mu$ l of crystal violet solution (1% crystal violet, 1% HCl, and 10% ethanol) at 37 °C for 30 minutes. Absorbance measurements were performed on a microtiter plate reader at a wavelength of 570 nm. Absorbance values are presented as the mean of three wells per treatment  $\pm$  the standard deviation (SD).

## Glioblastoma Apoptosis and EGFR Cellular Signaling Studies after IONP Treatment

Glioblastoma cells (U87MG, U87 $\Delta$ EGFRvIII, and U87wtEGFR) and neurospheres from Patients #30 and 74 were seeded in 6-well flat-bottomed plates (500,000 cells/well) and incubated overnight at 37 °C. Cells were treated with control IgG (0.3 mg/ml), IONPs (0.3 mg/ml), EGFRvIIIAb (0.3 mg/ml), and EGFRvIIIAb-IONPs (0.3 mg/ml) for 2–3 h in PBS at 37°C. Cells were lysed in RIPA buffer (50mM Tris, pH 8.0, 150 mM NaCl, 5 mM EDTA, and 1% NP40, with protease and phosphatase inhibitors). Western blot analysis of protein levels were performed with primary antibodies against cleaved caspase-3 and caspase-3 antibody (Cell Signaling) according to the manufacturer's recommended conditions

For EGFR signaling studies, glioblastoma cells were treated with control (PBS), IONPs (0.5 mg/ml), EGFRvIIIAb (0.5 mg/ml), and EGFRvIIIAb-IONPs (0.5 mg/ml) for 2 hours in PBS at room temperature. Cell lysates were harvested in RIPA buffer (50mM Tris, pH 8.0, 150 mM NaCl, 5 mM EDTA, and 1% NP40, with protease and phosphatase inhibitors). Western blot analysis of protein levels were performed with primary antibodies against, phospho EGFR (Transduction Laboratories), phospho Akt (Cell Signaling), Akt (Cell Signaling), phospho ERK 44/42 (Cell Signaling), and ERK 44/42 (Cell Signaling) according to the manufacturer's recommended conditions. Horseradish peroxidase (HRP)-conjugated secondary antibodies (Dako) and treatment with a chemoluminescent HRP detection solution (Denville Scientific, Inc.) was used to detect the proteins.

## Tumor Inoculation and IONP Convection Procedure

Anesthetized athymic nude mice were placed in the stereotaxic instrument and U87 $\Delta$ EGFRvIII cells ( $5 \times 10^5$ ) were stereotactically inoculated into the right striatum, 3 mm below the dural surface on day 0. On day 7 post-tumor implantation, mice were randomized into four groups: (1) CED of HBSS (untreated control), (2) CED of IONPs, (3) CED of EGFRvIIIAb, (4) CED of EGFRvIIIAb-IONPs. All animals underwent CED of a 10  $\mu$ l volume at a rate of 0.5 $\mu$ l/min (20 minute total infusion) on the day 7 using the same coordinates as used earlier for tumor cell implantation. For the CED methods, please see Supplemental Methods.

## The Volume of Distribution ( $V_D$ ) and Volume of Dispersion ( $V_{DI}$ ) of IONPs after CED

Mice inoculated with U87 $\Delta$ EGFRvIII cells ( $5 \times 10^5$ ) were also followed by MRI to investigate the initial  $V_D$  and  $V_{DI}$  of IONPs over a period of 11 days after CED. Animals underwent CED of IONPs (N=3 free IONPs and N=3 EGFRvIIIAb-IONPs) as described

above on day 9 post tumor implantation. These animals were scanned on a 4.7T animal MRI scanner using a dedicated mouse coil (Varian Unity) on days 0, 4, 7, and 11 after CED. A  $V_D$  was determined for each animal (N= 4) days 0, 4, 7, and 11 after CED. The volume of dispersion ( $V_{DI}$ ) of the IONPs on days 4, 7, and 11 were determined by subtracting the  $V_D$  at day 0 from the  $V_D$  calculations on days 4, 7, and 11 after CED of the IONPs (e.g.,  $V_{DI}$  day 4 =  $V_D$  day 4 –  $V_D$  day 0). For  $V_D$  and  $V_{DI}$  measurements please see the Supplemental Methods.

## Histology

Mouse brains were harvested and fixed with 10% neutral buffered formalin days 7 and 9 post tumor implantation. Coronal sections were made at the level of the needle tract to mark the center of the xenograft tumor. Serial sections of the cerebral hemisphere were examined from each animal. Tissue blocks were embedded in paraffin and sectioned (5 micrometers). Prussian blue staining was performed after slides of formalin-fixed tissue were placed in a coplin jar containing a 1:1 mixture of 5% potassium ferrocyanide and 5 % HCl acid for 30 min at 37°C in a water bath. The slides were rinsed well with distilled water and counterstained with nuclear fast red for 20 min (Fig. S4). EGFRvIII immunohistochemistry was performed (day 7 post tumor implantation) after deparaffination of tissue sections (Fig. S5). The primary rabbit polyclonal EGFRvIII antibody (GenScript Corp., Piscataway, NJ) and a biotinylated anti-rabbit secondary antibody provided in a rabbit ABC staining system (sc-2018; Santa Cruz Biotechnology, Santa Cruz, CA) were used.

## Animal Survival Studies

All athymic nude mice were observed daily to monitor external appearance, feeding behavior, and locomotion. Animals were sacrificed at the first sign of an adverse event (paresis, inability to feed) and brains were removed.

## Statistical Analysis

Cell viability data represents the average of three independent absorbance values on day 3 of the crystal violet assay. Statistical cell viability differences were assessed using an unpaired two-sample Student's *t* test assuming equal variance. Animal survival data were entered into Kaplan-Meier plots and statistical analysis was performed using a log-rank test. A probability value of 0.05 was used as the boundary of statistical significance.

## Results

### EGFRvIIIAb-IONP Bioconjugate

Amphiphilic triblock copolymer coated IONPs (10 nm in size; provided by Ocean Nanotech, LLC, Fayetteville, AR) were covalently conjugated to a purified rabbit polyclonal EGFRvIIIAb (Fig. S1). The IONP surface coating provides a stable hydrophobic protective inner layer around a single crystal of IONP with carboxylate groups in the outer layer for functionalization (29). Bioconjugation was performed with the amino-terminal fragment of the antibody and carboxyl groups on the copolymer coating of the IONPs (Fig. 1). Confirmation of the antibody conjugation to IONPs was performed by agarose gel electrophoresis analysis (Fig. S3)

### Confirmation of Binding of EGFRvIIIAb –IONPs to Human Glioblastoma Cells by MRI and TEM

The binding affinity of EGFRvIIIAb-IONPs to human GBM cells that overexpress the EGFRvIII mutated protein was evaluated. The EGFRvIIIAb-IONP conjugate was able to selectively bind to U87ΔEGFRvIII cells and induce T<sub>2</sub> weighted MRI contrast enhancement

after 1 and 2 hours of treatment (Fig. 2; Table 1) as evidenced by the MRI signal drops compared to the control samples of cells treated with free IONPs. Such strong  $T_2$  shortening and the magnetic susceptibility effects of IONPs lead to spin dephasing and substantial MRI signal drop which generated a “darkening” contrast as seen in the  $T_2$  weighted MR images. Transmission electron microscopy (TEM) confirmed binding of EGFRvIIIAb-IONPs to the cell surface of an EGFRvIII-expressing glioblastoma cells as shown in (Fig. S6). No evidence of endocytosis and endosome-filled EGFRvIIIAb-IONPs were found in glioblastoma cells based on TEM. In contrast, treatment of cells with free IONPs, revealed nonspecific cell surface binding, uptake, and IONP-filled endosomes within the cytoplasm of U87 $\Delta$ EGFRvIII cells (Fig. S7).

### IONPs Exhibit No Toxicity to Human Astrocytes

To determine whether IONPs are toxic to human astrocytes, cells were treated with control vehicle (serum-free medium) or IONPs (0.3 mg/ml) for 1 hour. After cell washing, a crystal violet cell viability assay was performed. There was no significant toxicity found with human astrocytes 3 days after treatment with IONPs ( $P < 0.001$ ) (Fig. 3A).

### Antitumor Effect of IONPs on Human Glioblastoma Cells

Human glioblastoma cells (U87-MG or U87 $\Delta$ EGFRvIII) were incubated with control (PBS), EGFRvIIIAb, IONPs, or EGFRvIIIAb-IONPs for 1 hour (Fig. 3B and C). Cells were washed and a cell viability assay was performed at 0, 1, and 3 days after treatment. At day 3, there was a significant decrease in cell survival in U87 $\Delta$ EGFRvIII cells treated with IONPs, EGFRvIIIAb, or EGFRvIIIAb-IONPs ( $P < 0.001$ ). There was a less pronounced but statistically significant decrease in cell survival in U87MG cells treated with IONPs, EGFRvIIIAb, or EGFRvIIIAb-IONPs ( $P < 0.01$ ). Nonspecific uptake of free IONPs likely accounts for cell toxicity and the antitumor effect found in both glioblastoma cell lines (Fig. S7).

### Apoptosis as Mode of GBM Cell and GSC-Containing Neurosphere Death after EGFRvIIIAb-IONP Treatment

Human glioblastoma cells (U87MG, U87 $\Delta$ EGFRvIII, and U87wtEGFR) and neurospheres were incubated with control IgG, EGFRvIIIAb, IONPs, and EGFRvIIIAb-IONPs (Fig. 4). Western blot analysis revealed elevated levels of cleaved caspase-3 in glioblastoma cells (Fig. 4A) and neurospheres (Fig. 4B) treated with EGFRvIIIAb-IONPs. No levels of cleaved caspase-3 were found with treatment of glioblastoma cells with free IONPs, control IgG, or EGFRvIIIAb. Elevated levels of cleaved caspase-3 and apoptosis were found in human glioblastoma neurospheres harvested from Patients #30 and 74 after treatment by the EGFRvIIIAb-IONPs (Fig. 4B). Glioblastoma neurospheres from Patient #30 are characterized by EGFRvIII, wild-type (wt) EGFR, and the CD133 glioblastoma stem cell (GSC) marker expression while neurospheres from Patient #74 express wt EGFR (Fig. S2).

### Glioblastoma EGFR Signaling and IONPs

Ligand activation of the EGFR leads to a series of downstream signaling events after phosphorylation and activation (30,31). Western blot analysis of EGFR cellular signaling proteins was performed in glioblastoma cells (U87MG, U87wtEGFR, and U87 $\Delta$ EGFRvIII) treated with control (PBS), IONPs, EGFRvIIIAb, or EGFRvIIIAb-IONPs (Fig. 4C). Levels of phosphorylated EGFR, phospho Akt, Akt, ERK 44/42, and phospho ERK 44/42 were determined. Both U87wtEGFR and U87 $\Delta$ EGFRvIII showed elevated levels of phosphorylated EGFR as expected due to the overexpression of the EGFR in these cell lines. The U87 $\Delta$ EGFRvIII cells showed the greatest EGFR phosphorylation due to the constitutive activity of the EGFRvIII receptor. Treatment of these cells with the EGFRvIIIAb-IONPs

demonstrated a lower level of EGFR phosphorylation. Treatment of the U87wtEGFR and U87ΔEGFRvIII glioblastoma cells with either IONPs or EGFRvIIIAb-IONPs resulted in less phosphorylation of Akt and no phosphorylation of ERK, suggesting that IONPs may affect downstream EGFR signaling in glioblastoma cells. Treatment of the U87wtEGFR and U87ΔEGFRvIII glioblastoma cells with EGFRvIIIAb alone resulted in an increase in phosphorylated Akt and ERK levels.

### CED of EGFRvIIIAb-IONPs in a Mouse Glioma Model

Athymic nude mice (n=6) implanted with human GBM xenografts that express the mutated EGFRvIII protein (U87ΔEGFRvIII) underwent CED of EGFRvIIIAb-IONPs (n=3) or IONPs (n=3) in aqueous solution (0.2 mg/ml concentration; 10 μl volume; 0.5 μl/min rate for a total of 20 minutes) nine days after tumor implantation. MRI was performed prior to CED to confirm proper growth of the xenograft in each mouse brain (Fig. 5) and then 0, 4, 7, and 11 days after CED of the nanoparticles to determine localization, initial volume of distribution ( $V_D$ ), and volume of dispersion ( $V_{DI}$ ) of the IONPs administered (Fig. 5). Average  $V_D$  values were 11.2, 19.2, 22.7, and 22.9 (mm<sup>3</sup>) on days 0, 4, 7, and 11, respectively. The averaged  $V_{DI}$  values were 8.0, 11.5, 15.5 (mm<sup>3</sup>) on days 4, 7 and 11 after CED. There was no statistical significant difference in the  $V_D$  and  $V_{DI}$  of free IONPs and EGFRvIIIAb-IONPs. Prussian blue staining was performed to confirm the presence of the EGFRvIIIAb-IONPs in human xenograft tumors and the surrounding mouse brain after CED (Fig. S4).

Several initial findings support the feasibility of the MRI guided CED of IONPs in human xenograft brain tumors: 1) EGFRvIIIAb-IONPs can be distributed within or adjacent to brain tumors with CED; 2) outstanding contrast induced by IONPs enables MRI to monitor and follow the distribution of the nanoparticle complex in the tumor and in the surrounding brain after CED; 3) intracerebral infusion is safe as all animals survived from the procedures and showed no signs of toxicity; 4) CED led to a long retention of the EGFRvIIIAb-conjugated nanoparticles and slow dispersion of the agents at the tumor site as shown on MRI; 5) MRI can delineate and quantify the extent of dispersion of the IONP complex after CED with T<sub>2</sub> weighted MRI.

### Animal Survival Studies and Therapeutic Efficacy of EGFRvIIIAb-IONPs after CED

Animal survival studies were performed in 4 groups of mice implanted with highly tumorigenic U87ΔEGFRvIII xenografts (Fig 6; Fig. S5). Each group of animals (n=10) underwent CED of control (HBSS), unconjugated IONPs (0.2 mg/ml), EGFRvIIIAb (0.2 mg/ml), or EGFRvIIIAb-IONPs (0.2 mg/ml) seven days after tumor implantation. All the animals which underwent HBSS CED were dead by 14 days after tumor implantation (median survival 11 days). A significant increase in survival was found in animals that underwent the CED of IONPs (median survival 16 days), EGFRvIIIAb (median survival 17 days), EGFRvIIIAb-IONPs (median survival 19 days) in comparison to HBSS ( $P < 0.001$ ). Both the EGFRvIIIAb and EGFRvIIIAb-IONP treatment groups have a single survivor after 120 days of survival studies.

### Discussion

Accurate targeting and better delivery efficiency are two major goals in the development of therapeutic agents for the treatment of malignant brain tumors. Ideally, a therapeutic agent would be able to overcome the BBB and selectively be enriched in tumors with minimal toxicity to normal tissues. Conjugation of agents to antibodies or other ligands that bind to antigens or receptors that are usually abundantly or uniquely expressed on the tumor surface represent a promising approach for treatment of glioblastoma tumors and have been taken to

clinical trials (32,33). Unfortunately, the ability to image therapeutic agents in the brain for adequate tumor delivery and proper assessment of treatment efficacy remains a limiting factor.

The use of nanotechnology is now being applied to CNS cancer applications (13,25,34–39). One potential problem that can attenuate the targeted therapy and imaging of CNS tumors by systemic delivery of nanoparticles is their being “trapped” in the liver, spleen, and circulating macrophages after intravenous administration due to non-specific uptake. Additionally, systemic delivery is also limited by the BBB, nontargeted distribution, and systemic toxicity. CED is an approach developed to overcome the obstacles associated with current CNS agent delivery (26,27,40) and is increasingly used to distribute therapeutic agents for treatment of malignant gliomas (27). Recently, multiple clinical trials have been performed utilizing CED for the treatment of recurrent GBM (32,33,41). In CED, a small hydrostatic pressure differential imposed by a syringe pump to distribute infusate directly to small or large regions of the CNS is used in a safe, reliable, targeted, and homogeneous manner (42). Difficulty imaging CED of therapeutic agents in the brain is one major limitation of this approach. Groups have radio-labeled their therapeutic agent, co-infused their agent with radio-labeled albumin ( $^{125}\text{I}$ -labeled albumin), or used liposomes containing an MRI contrast agent (e.g., gadoteridol) for CED imaging (33,43,44). Radio-labeling of therapeutic agents relies on single-photon emission computerized tomography (SPECT) for agent imaging which is a low resolution imaging modality of the brain. Co-infusion of an MRI contrast agent or radio-labeled albumin may not allow for precise therapeutic agent distribution analysis in the brain due to the differences in molecular weight and surface properties between each infusate. Recently, CED of biodegradable, nonfunctionalized maghemite magnetic nanoparticles have been depicted by MRI in a normal rat brain model (45). Direct imaging of magnetic nanoparticles by MRI can permit distribution studies of nanoparticles in the brain after CED.

Currently, two major types of systemic anti-EGFR agents have entered the clinical setting: anti-EGFR antibodies and small-molecule EGFR tyrosine kinase inhibitors (TKIs) (46–48). These agents have shown modest efficacy in patients with GBM tumors. The development of new agents that can target the EGFR deletion mutant, EGFRvIII, can permit direct targeting of glioblastoma cells while sparing the normal brain (9,49–52). Furthermore, the targeting of glioblastoma stem cells (GSC) and/or GSC-specific molecules (e.g., CD133) may form the basis of more effective treatments against glioblastoma tumors and prevention of relapse (2).

We report for the first time the use of IONPs bioconjugated to an EGFRvIII deletion mutant antibody for MRI-assisted CED and targeted therapy of human glioblastoma. The bioconjugated EGFRvIIIAb-IONPs permit MRI contrast enhancement or “darkening” of U87ΔEGFRvIII cells with  $T_2$  weighted MRI. The EGFRvIIIAb-IONPs caused a significant decrease in glioblastoma cell survival and a greater antitumor effect was found after treatment of EGFRvIII-expressing glioblastoma cells with EGFRvIIIAb-IONPs in comparison to human glioblastoma cells which did not express the EGFR. This provided further evidence of a biomarker targeting effect by the EGFRvIIIAb-IONPs. The pronounced antitumor effect of free IONPs with glioblastoma cells is likely due to the nonspecific uptake of the nanoparticles by the tumor cells. Uptake of IONPs by glioma cells have been shown in culture and *in vivo* in the past (53,54). The influence of surface functionalization has recently been shown to enhance the internalization of magnetic nanoparticles in cancer cells (55). Our IONPs are functionalized through surface coating of amphiphilic polymers which may promote uptake within glioblastoma cells and result in cell toxicity.

No significant toxicity was found with IONP treatment of human astrocytes or in animals after intracerebral administration. No toxicity to human astrocytes and a significant killing effect of both free IONPs and EGFRvIIIAb-IONPs form the basis of targeted therapy of GBM cells in the brain. Apoptosis was determined to be a mode of cell death after treatment of glioblastoma cells and neurospheres by the conjugate, EGFRvIIIAb-IONP. Apoptosis was found after treatment of GSC-containing neurospheres harvested from a glioblastoma patient (Patient #30) with elevated expression of EGFRvIII and the GSC marker CD133. While we were not able to find apoptosis induction in glioblastoma cells after treatment with free IONPs or the EGFRvIIIAb alone, a significant antitumor effect was found both in vitro and in our animal survival studies. Mechanistic studies suggest EGFR downstream signaling may be affected by IONPs with less EGFR phosphorylation after glioblastoma cell treatment with the EGFRvIIIAb-IONPs. Furthermore, IONPs resulted in less phosphorylation of Akt and ERK in glioblastoma cells overexpressing the EGFR.

CED of IONPs in a mouse glioma model results in MRI contrast of the nanoparticles and effective intratumoral and peritumoral distribution of nanoparticles in the brain. A significant therapeutic effect was found after CED of both IONPs and EGFRvIIIAb-IONPs in mice. Dispersion of the nanoparticles over days, after the infusion has finished, may potentially target infiltrating tumor cells outside the tumor mass that are potentially responsible for tumor recurrence and the demise of patients. Use of bioconjugated magnetic nanoparticles may permit the advancement of CED in the treatment of malignant gliomas due to their sensitive imaging qualities on standard T<sub>2</sub> weighted MRI and therapeutic effects. Better targeting of infiltrative glioblastoma tumors by MRI-guided CED of magnetic nanoparticles may provide more effective treatment of these devastating brain tumors. We recognize the rodent model may not be the ideal animal model to study CED, however, our studies provide a proof of principle concept for future CED studies utilizing other cancer nanotechnology agents.

In conclusion, the preclinical use of IONPs conjugated to a glioblastoma specific antibody, may form the basis of a future clinical trial of image-guided CED of magnetic nanoparticles for patients with glioblastoma tumors.

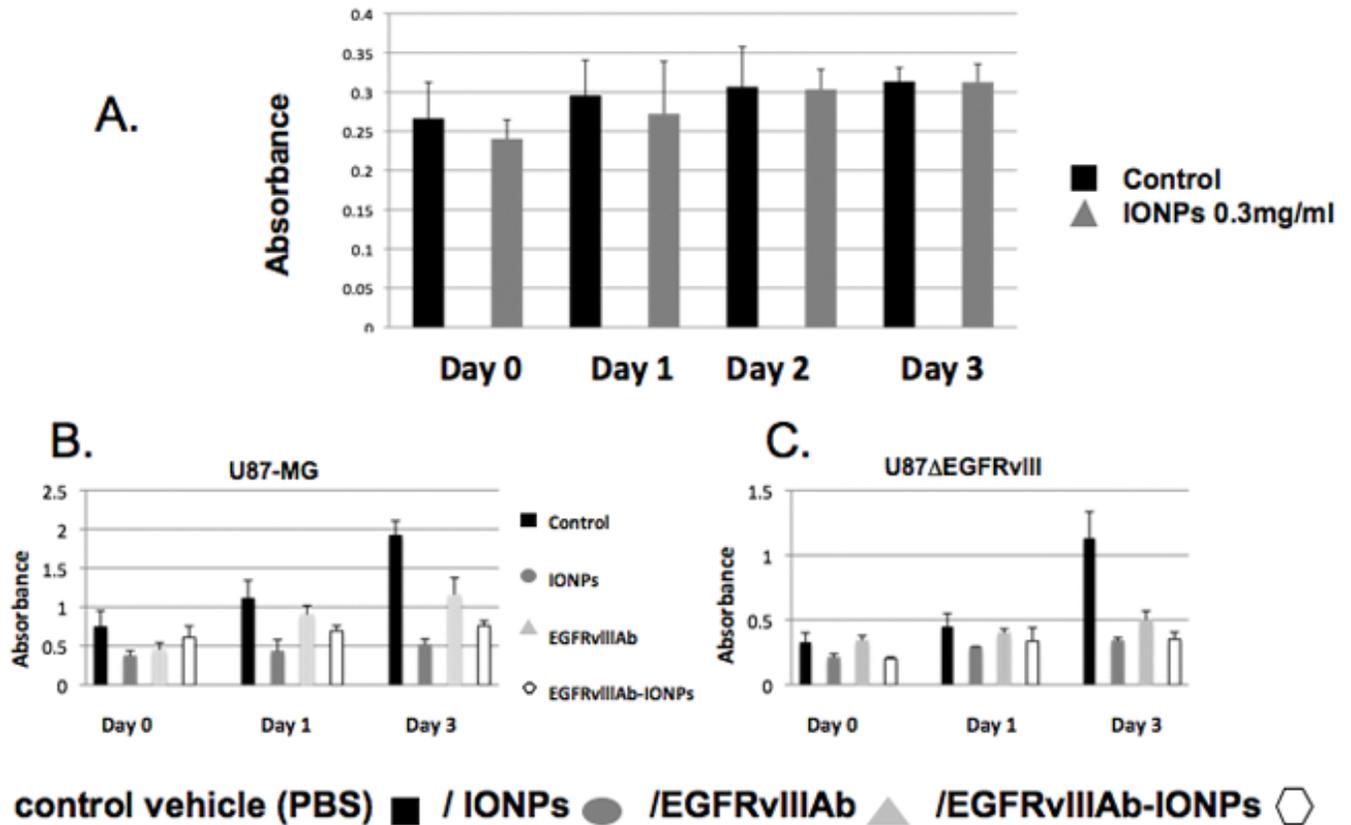

**Figure 1. Amphiphilic blocked polymer coated IONPs conjugated to the EGFRvIIIAb**  
 Illustration of IONP (shown in red; core size of 10 nm) coated with a biocompatible amphiphilic copolymer bioconjugated to the EGFRvIIIAb (Illustration provided by Eric Jablonowski, Dept. of Radiology, Emory University School of Medicine). Polyethylene glycols (PEG) are present on the surface of the polymer for further stabilization and biocompatibility of the IONP. Bioconjugation of the EGFRvIII antibody is performed to the -COOH of the polymer coating of the IONP.

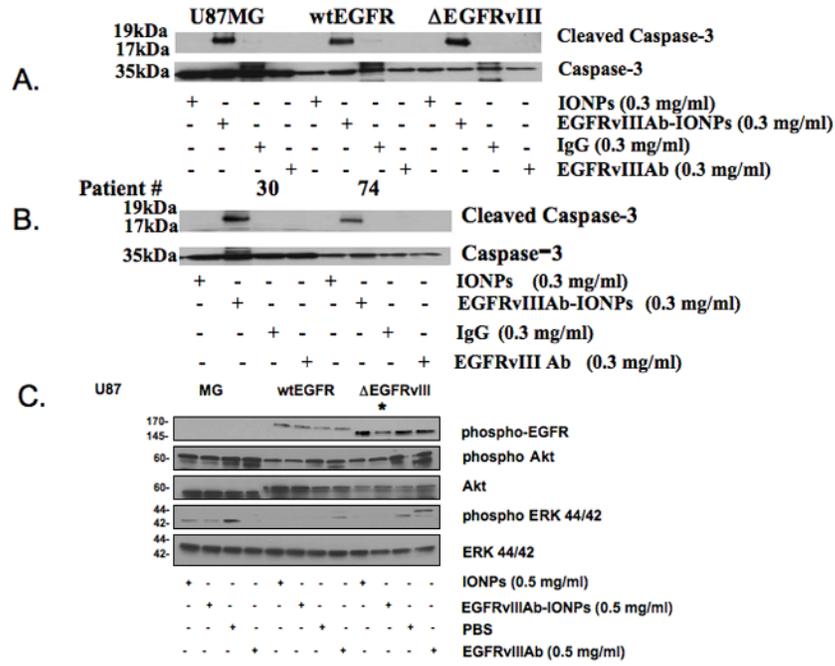

**Figure 2. Binding of EGFRvIIIAb-IONPs to human glioblastoma cells and MRI contrast enhancement**

The binding of EGFRvIIIAb-conjugated IONPs to human GBM cells that overexpress the EGFRvIII mutated protein was confirmed by MRI contrast changes (lower signal intensity at longer TE in T<sub>2</sub>-weighted imaging and reduction of T<sub>2</sub> values in Table 1 as shown in B and C after 1 and 2 h of treatment) when compared to the control samples of free IONPs (A).

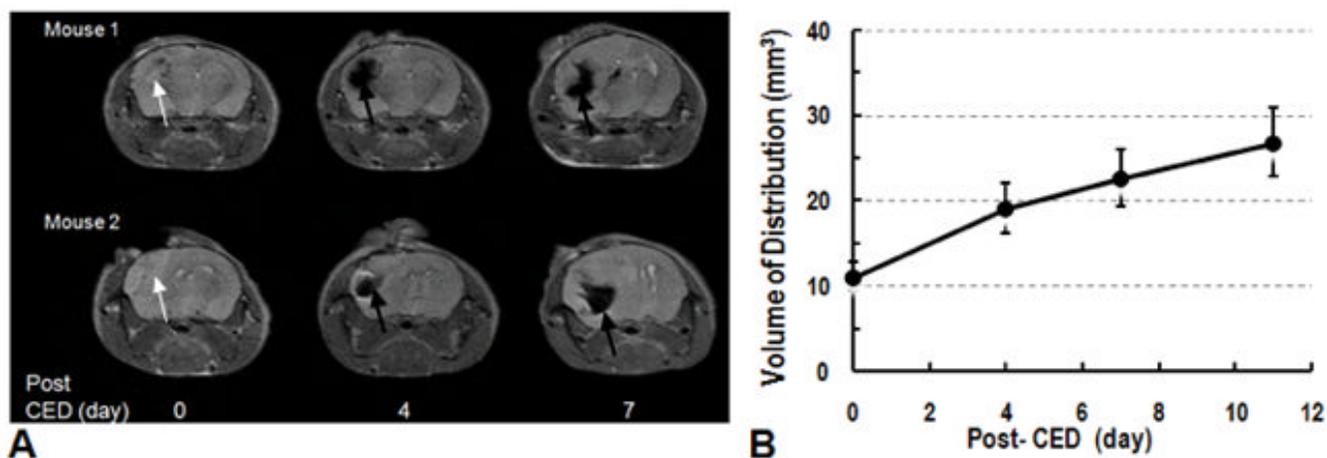

**Figure 3. Cell toxicity analysis of human astrocytes and glioblastoma cells treated with IONPs**  
**A.**, Human astrocytes were treated with control vehicle (serum-free medium) or IONPs. at 0, 1, 2, and 3 days. No significant toxicity was found with IONP treatment of human astrocytes ( $P < 0.001$ ). Cell toxicity analysis of human glioblastoma cells (**B.** U87-MG and **C.** U87ΔEGFRvIII) after treatment by control vehicle (PBS), IONPs, EGFRvIIIAb, and EGFRvIIIAb-IONPs at 0, 1, and 3 days. A significant decrease in cell survival was found in glioblastoma cells treated by IONPs, EGFRvIIIAb, and EGFRvIIIAb-IONPs at 3 days ( $P < 0.001$ ).

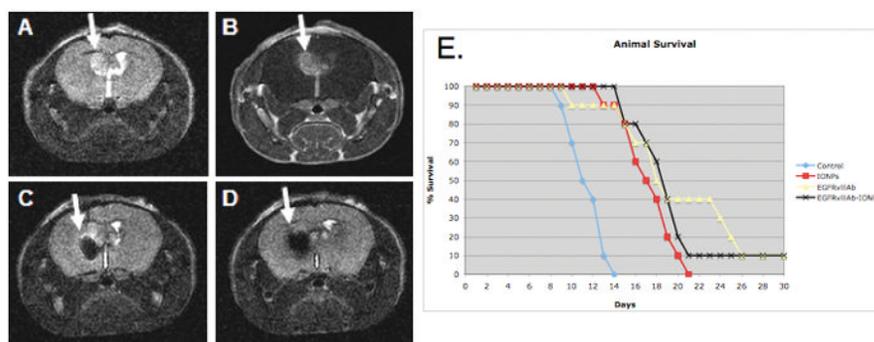

**Figure 4. Apoptosis studies and glioblastoma EGFR cellular signaling after treatment with EGFRvIIIAb-IONPs**

**A.**, Elevated levels of cleaved caspase-3 and apoptosis were found in all human glioblastoma cells (U87MG, U87ΔEGFRvIII, and U87wtEGFR) after treatment with EGFRvIIIAb-IONPs. **B.**, Elevated levels of cleaved caspase-3 and apoptosis were found in human glioblastoma neurospheres harvested from Patients #74 and 30 after treatment with EGFRvIIIAb-IONPs. **C.**, Glioblastoma EGFR cellular signaling after treatment with IONPs, EGFRvIIIAb-IONPs, control vehicle (PBS), and EGFRvIIIAb. Western blot analysis of glioblastoma cells (U87MG, U87wtEGFR, and U87ΔEGFRvIII) reveals less of the phosphorylated and active form of EGFR (\*) in U87ΔEGFRvIII cells after treatment with EGFRvIIIAb-IONPs.

**Figure 5. CED of EGFRvIIIAb-IONPs in a mouse glioma model**

**A.** Examples of  $T_2$  weighted images of mouse brains (Mouse 1 and Mouse 2) show the presence of intracranial xenograft (shown by white arrows) and reveal localization, distribution, and dispersion of magnetic nanoparticles days 4, and 7 after CED (shown by black arrows).  $T_2$ -weighted MRI showed decrease of signal after CED of IONPs. Areas with signal drop increased 7 days after CED showing dispersion of nanoparticles. **B.**, Initial nanoparticle volume of distribution ( $V_D$ ) after CED is shown at day 0. The volume of dispersion ( $V_{DI}$ ) was determined at 4, 7, and 11 days after CED confirming dispersion of nanoparticles.

**Figure 6. Survival studies of athymic nude mice implanted with human U87 $\Delta$ EGFRvIII xenografts after magnetic nanoparticle CED**  
**A.**, T<sub>2</sub> weighted MRI showing a tumor xenograft with bright signal 7 days post tumor implantation (arrow); **B.**, Tumor shown (arrow) by contrast enhancement after injection of the gadolinium contrast agent (Gd-DTPA); **C.**, MRI signal drop (arrow) after CED of EGFRvIIIAb-IONPs; **D.**, EGFRvIIIAb-IONP dispersion and T<sub>2</sub> signal drop (arrow) on MRI 4 days after CED. **E.**, Kaplan-Meier survival curve comparison of athymic nude mice after intracranial implantation of human U87 $\Delta$ EGFRvIII cells and treatment by MRI guided CED of HBSS (control), IONPs, EGFRvIIIAb, or EGFRvIIIAb-IONPs. Statistical significance,  $P < 0.001$ , was estimated by log-rank method of CED of EGFRvIIIAb-IONPs, IONPs, and EGFRvIIIAb compared to HBSS CED.

**Table 1**  
**MRI T<sub>2</sub> values after treatment of U87ΔEGFRvIII cells with free IONPs or EGFRvIIIAb-IONPs**

**A.**, Cells were treated with free IONPs for 1 h; **B. and C.**, A reduction in T<sub>2</sub> values (MRI contrast enhancement) was found after glioblastoma cells were treated for 1 and 2 h with EGFRvIIIAb-IONPs (shown in red).

	Sample	T <sub>2</sub> (cal.) s <sup>-1</sup>
A	U87ΔEGFRvIII cells + IONPs 2h	0.053
B	U87ΔEGFRvIII cells + EGFRvIII Ab-IONPs 1h	0.037
C	U87ΔEGFRvIII cells + EGFRvIIIAb-IONPs 2h	0.026
