Key Points

- In persons of AA, a polygenic risk score in the top 10% (compared with 25%-75%) is associated with an 80% increased multiple myeloma risk.
- Common genetic variation contributes to the risk of multiple myeloma in men and women of AA.

Persons of African ancestry (AA) have a twofold higher risk for multiple myeloma (MM) compared with persons of European ancestry (EA). Genome-wide association studies (GWASs) support a genetic contribution to MM etiology in individuals of EA. Little is known about genetic risk factors for MM in individuals of AA. We performed a meta-analysis of 2 GWASs of MM in 1813 cases and 8871 controls and conducted an admixture mapping scan to identify risk alleles. We fine-mapped the 23 known susceptibility loci to find markers that could better capture MM risk in individuals of AA and constructed a polygenic risk score (PRS) to assess the aggregated effect of known MM risk alleles. In GWAS meta-analysis, we identified 2 suggestive novel loci located at 9p24.3 and 9p13.1 at \( P < 1 \times 10^{-8} \); however, no genome-wide significant association was noted. In admixture mapping, we observed a genome-wide significant inverse association between local AA at 2p24.1-23.1 and MM.

The microarray data reported in this article have been deposited in the database of Genotypes and Phenotypes (accession number phs001632.v1.p1). The full-text version of this article contains a data supplement.
risk in AA individuals. Of the 23 known EA risk variants, 20 showed directional consistency, and 9 replicated at \( P < .05 \) in AA individuals. In 8 regions, we identified markers that better capture MM risk in persons with AA. AA individuals with a PRS in the top 10% had a 1.82-fold (95% confidence interval, 1.56-2.11) increased MM risk compared with those with average risk (23%-75%). The strongest functional association was between the risk allele for variant rs56219066 at 5q15 and lower ELL2 expression \( (P = 5.1 \times 10^{-12}) \). Our study shows that common genetic variation contributes to MM risk in individuals with AA.

**Introduction**

Multiple myeloma (MM) originates from a malignant clone of plasma cells, the terminally differentiated B-lymphocytes that produce antibody upon antigen recognition. It is the second most common hematologic malignancy in the United States, with \( \sim 160,000 \) new cases in 2018,\(^7\) and remains largely incurable, with a 50% 5-year survival rate. Older age, male sex, African ancestry (AA), family history, and obesity, especially in young adulthood, are factors consistently associated with MM risk.\(^2\)-\(^4\) In the United States, the incidence rate of MM is twice as high in men and women of AA compared with those of European ancestry (EA), for unknown reasons.\(^2\) Case reports of familial clustering\(^5\) and a two- to threefold increased risk among first-degree relatives\(^6,7\) suggest a genetic contribution to the etiology of MM. We previously showed that 5 of 8 risk loci identified in persons of EA also contribute to risk in persons of AA.\(^8\)-\(^10\) Fifteen new MM risk loci have been identified in EA populations,\(^11\)-\(^13\) but these have not been examined in populations of AA. Moreover, no genome-wide significant associations have been identified that explain MM risk specifically for AA individuals. Here, we added a second genome-wide association study (GWAS) in a meta-analysis, for a total of 1813 cases and 8871 controls, to assess the association between common genetic variation and MM risk in the largest study of cases and controls of AA conducted to date.

**Methods**

All studies contributing DNA samples had approval from their Institutional Review Boards according to the Declaration of Helsinki Ethical Principles for Medical Research for Human Subjects (1964). Signed informed consent was obtained from all participants at the time of specimen collection.

**Study participants, genotyping, and quality control**

There were 2 sets of study participants. Set 1 was a GWAS case-control study that was previously conducted in 1179 AA MM patients identified from 11 National Cancer Institute (NCI) comprehensive cancer centers and nonprofit hospitals and 4 NCI Surveillance, Epidemiology, and End Results cancer registries participating in the African American Multiple Myeloma Study in 2010 to 2015. In addition, DNA samples from the Multiethnic Cohort Study \((n = 43)\), the University of California at San Francisco study \((n = 32)\), and the Multiple Myeloma Research Consortium \((n = 84)\) were included \((total N = 1338 cases)\), as described elsewhere.\(^8\) Controls were AA subjects unaffected by MM and with existing GWAS data, including 2631 female controls from the African Ancestry Breast Cancer Consortium\(^14\) and 4447 male controls from the African Ancestry Prostate Cancer Consortium.\(^15\) Cases were genotyped using the Illumina HumanCore GWAS array, whereas controls were genotyped using the Illumina 1M-Duo. Quality control (QC) measures for cases and controls were conducted separately. Cases with call rate \( < 0.98 \) (\( n = 11 \)), unexpected replicates \((n = 14)\), first- or second-degree relatives \((n = 2)\), and those who were sex discordant based on \( X \) chromosome genotypes \((n = 6)\) were excluded.\(^8\) Single nucleotide polymorphisms (SNPs) with a call rate \( < 0.98 \) or replicate concordance \( < 1 \) based on 100 QC replicate samples were removed. QC procedures among controls were reported previously.\(^14,15\) Only SNPs that passed QC measures directly genotyped in both cases and controls were included in the imputation \((n = 188,376)\).

Set 2 consisted of DNA samples from 421 AA MM patients from the Myeloma Center, University of Arkansas for Medical Sciences and 132 additional samples from continued enrollment in the African American Multiple Myeloma Study in 2016 (primarily from the MD Anderson Cancer Center) \((total N = 553 cases)\). Controls were 2398 unaffected AA participants from the Multiethnic Cohort Study with existing GWAS data. Both cases and controls in Set 2 were genotyped using the Illumina MEGA array \((total genotyped SNPs \sim 1.7 million)\). Cases and controls were subjected to the same QC procedures. One case and 1 control were removed because of cross-set replication. Additional individuals were removed based on call rate \( < 0.95 \) \((n = 3)\), sex mismatch \((n = 13)\), ancestry outlier \((estimated African [AFR] global ancestry \( < 0.1 \) by STRUCTURE\(^16\); \( n = 4 \)) and 1 in a first-degree relative pair \((estimated sharing identity by descent \( \geq 0.375 \) by PLINK; \( n = 10)\), leaving 529 cases and 2389 controls for imputation. Control data were cleaned previously combined with the National Human Genome Research Institute Population Architecture Using Genomics and Epidemiology Consortium (NHGRI PAGE) samples\(^17\); thus, we first excluded SNPs that were low quality in these samples. Further SNP QC included removing nonmonomorphic SNPs, variants with a call rate \( < 0.98 \), replication concordance \( < 1 \) based on 10 replicate pairs in cases, cross-platform replication concordance \( < 100\% \) based on 8 replicate pairs in cases and controls, and SNPs with poor clustering by visual inspection. Additional removal criteria included SNPs with minor allele frequency (MAF) that deviated from the AFR individuals in the phase 3 1000 Genome Project (1KGP) data and indels not identified within 1KGP. SNPs found in both cases and controls were used for imputation \((N = 1,046,801)\). Shared identity by descent for Set 1 and Set 2 was calculated using PLINK to remove duplicate samples across sets. We excluded 21 cases and 571 controls from Set 1 that were included in Set 2, leaving a final analysis sample size for Set 1 of 7766 \((1284 cases\)
and 6482 controls). Genotyping, QC, and imputation procedures are described in supplemental Figure 1.

**Imputation**

For this analysis, Set 1 and Set 2 data were imputed using the same protocol. Genotype data were phased using SHAPEIT\(^\text{18}\) and then imputed to a cosmopolitan reference panel from the HaploTYPE Reference Consortium release 1 (N = 32,488 in total; n = 661 AFR)\(^\text{19}\) using the Michigan Imputation Server. We excluded SNPs with imputation quality score \(r^2 < 0.5\) and MAF < 0.01 in each dataset, leaving a total of 12,683,648 overlapping SNPs in Set 1 and Set 2 for statistical analyses.

**Statistical analyses**

**GWAS analysis.** Principal components (PCs) were calculated using EIGENSTRAT\(^\text{20}\) Risk allele frequencies (RAFs) were calculated by taking the average frequencies in Set 1 and Set 2 per-sex groups. Per-allele odds ratios (ORs) and standard errors were estimated using unconditional logistic regression, adjusted for age, sex, and the first 10 PCs, separately for Set 1 and Set 2. A fixed-effect meta-analysis with inverse variance weights was used to obtain the combined effects for each SNP. The genome-wide significance level was \(\alpha = 5.0 \times 10^{-8}\).

**Admixture analysis.** We estimated local ancestry separately in Set 1 and Set 2 by RFMix v1.5.4\(^\text{21}\) using European (EUR) and AFR populations in phase 1 1KGP as reference. Genotyped SNPs that passed our QC and were present in both sets were included in the analysis. We calculated individual global ancestry by averaging local AA values across the 22 autosomal chromosomes. For local ancestry at each locus, we performed case-only and case-control analyses\(^\text{22}\) using regression models adjusted for age and sex, separately in each of the 2 GWAS datasets. The case-only analyses compared local ancestry with global ancestry, whereas in case-control analyses we tested whether the average deviation of local ancestry from global ancestry was the same between cases and controls. A fixed-effect meta-analysis was then conducted, using \(P < 1 \times 10^{-5}\) to define genome-wide significance. Continuous regions (adjacent regions with \(P < 1 \times 10^{-4}\)) that were significant in both case-only and case-control comparisons were considered suggestive risk regions for MM.

To identify the set of independent SNPs within the local ancestry signal region, we selected SNPs with marginal \(P < .001\) and conducted forward-selection logistic regression using inclusion criteria of .001, adjusting for age, sex, and global AFR ancestry. To examine whether the detected local ancestry signal could be explained by variant dosage, we compared the marginal and conditional \(P\) values and OR percentage changes in local ancestry using logistic regression, adjusting for age, sex, and the first 10 PCs, with and without additional adjustment for allele dosage. We adjusted for both known risk variants and the independent-risk SNPs within the local ancestry signal region.

**Association testing of known risk regions.** We were able to directly genotype or impute 23 known MM risk variants.\(^\text{9-13}\) rs34229995 was excluded because it is uncommon in the AA population (<1%); thus, the following analyses of known risk regions included 22 of the 23 reported EA risk alleles. Directional consistency of effect was defined as ORs in the AA MM meta-analysis that were in the same direction of effect (ie, >1) as those reported in the EA population. A nominal \(P\) value of .05 was used to determine statistical significance. We also examined the t(11;14) translocation MM-specific risk allele rs603965 at 11q13.3 in a pooled subset of our AA cases with that translocation (102 and 45 cases from Set 1 and Set 2, respectively), and in all 8871 controls, using logistic regression and adjusting for global AFR ancestry, age, sex, and set.

We used the 22 reported EA risk alleles as index markers to search for other markers within a \(\pm 250\)-kb region that could better capture MM risk in the AA participants (defined as a “better AA marker”). To minimize measurement error, we retained only those SNPs with high imputation quality \((r^2 \geq 0.8)\). In each region, we examined SNPs with pairwise correlation \((r^2) \geq 0.2\) with the index variant in the EA population in 1KGP likely to capture the functional allele. To reduce false-positive associations, only SNPs with a \(P\) value that was smaller by 1 order of magnitude compared with the index variant were defined as a putative “better” marker of risk in AA individuals. A secondary marker within the known risk region was defined as a marker that had weak correlation \((r^2 < 0.2)\) with the index SNP among the EUR and AFR populations in 1KGP and \(P < 1 \times 10^{-6}\) after conditioning on the index SNP.

**Polygenic risk score analysis.** The aggregate effect of known risk alleles was examined using a weighted polygenic risk score (PRS) for each individual: \(\text{PRS}_i = \sum_{m=1}^{C} \beta_m g_{mi}\), where \(g_{mi}\) is the risk allele dosage for individual \(i\) at SNP \(m\), \(C\) defines risk SNPs at 22 known MM susceptibility loci, and \(\beta_m\) is the weight for SNP \(m\). We explored 2 sets of weights for the index SNPs: the marginal log ORs published from EA populations and log ORs in our AA MM meta-analysis. We also substituted better AA markers for 8 index SNPs and used weights of AA MM log ORs. The risk score in each set was categorized according to its percentile (<10%, 10%-25%, 25%-75%, 75%-90%, and >90%), and the risk associated with each category was estimated relative to the interquartile range of 25% to 75% using logistic regression and adjusting for the first 10 PCs, age, and sex. The PRS was constructed separately for each set, the results were combined in a fixed-effect meta-analysis, and the interaction between age at diagnosis and PRS scores was tested.

**Expression quantitative trait loci analysis.** We performed an expression quantitative trait loci (eQTL) analysis using Affymetrix Human Genome U133 2.0 Plus Array data for CD138\(^\text{+}\) plasma cells isolated from bone marrow aspirates, as recently described,\(^\text{23}\) from 292 patients from the University of Arkansas for Medical Sciences included in the GWASs. Briefly, the expression data were preprocessed, and the probabilistic estimation of expression residuals method was applied to estimate nongenetic hidden confounders.\(^\text{24}\) Linear regression was used to test the association between the genotype of risk variants and gene expression of genes within 1 Mb, adjusting for probabilistic estimation of expression residuals factors. Risk variants, including suggestive novel signals, known markers identified from previous EA studies, and better AA markers, were examined in the eQTL analysis. A conservative Bonferroni-corrected \(P\) value of .0001 was used to determine statistical significance after correcting for 509 total tests.

**Results**

The GWAS meta-analysis indicated no evidence of overdispersion \((\lambda = 1.03)\). We did not observe any genome-wide significant
association (P < 5 × 10^{-8}) between common alleles and MM risk (supplemental Figure 2; supplemental Table 1). Seven regions harbored signals with P < 1 × 10^{-6}; however, the signal in 4 of them disappeared when a more stringent criterion (r^2 ≥ 0.8) was used to filter imputed SNPs (supplemental Table 1). The 2 remaining suggestive novel risk alleles were located at 9p24.3 (rs13296848; OR, 1.25; Wald P = 3.44 × 10^{-7}; RAF, 0.33 [cases] and RAF, 0.28 [controls]) and 9p13.1 (rs7034061; OR, 1.32; Wald P = 9.17 × 10^{-7}; RAF, 0.15 [cases] and RAF, 0.13 [controls]) (supplemental Figure 3).

In admixture mapping analysis, we found a region on chromosome 2 where lower local AA was statistically significantly associated with MM risk in both case-only and case-control comparisons (P < 1 × 10^{-5}), ranging from 23.1 to 29.8 Mb (2p24.1-2p23.1), which covered the known risk region at 2p23.3 (supplemental Figure 4; supplemental Table 2). The strongest local ancestry-MM association was observed at 28.8 to 29.2 Mb (2p23.2; OR per AFR chromosome, 0.79; 95% confidence interval [CI]: 0.72-0.88; P = 9.4 × 10^{-9}). The known risk allele rs6746082 in that region, which is more common in the EA population (RAF, 0.79) than in the AA population (RAF, 0.56), was not significantly associated with MM risk in AA individuals (Table 1). When conditioning on rs6746082, the local ancestry-MM association became only slightly less significant, implying that the known risk allele does not explain the admixture signal. However, when conditioning on our AA MM better marker rs10180663 (identified in fine-mapping), the signal was attenuated by our AA MM meta-analysis, this OR was 1.66 (95% CI, 1.43-1.94; P = 7.5 × 10^{-11}); when substituting the 8 index EA SNPs with their corresponding better AA markers, this association became slightly stronger (OR, 1.82; 95% CI, 1.56-2.11; P = 9.4 × 10^{-15}) (Table 2). The results of an unweighted PRS were similar (supplemental Table 4). We did not detect any significant interaction between PRS and age at diagnosis on MM risk (data not shown).

In an eQTL analysis (supplemental Table 3), of the 2 suggestive novel variants from the GWAS meta-analysis, only rs7034061 at 9p13.1 was found to be marginally associated (P = 0.046) with nearby gene expression (EXOSC3); however, it did not remain significant after correcting for multiple comparisons. Of the 22 known risk variants, the strongest association was observed for risk variant rs56219066 at 5q15, with the risk allele being associated with lower ELL2 expression (P = 5.1 × 10^{-12}). We also identified a significant association between the risk allele of rs2790457 at 10p12.1 and decreased expression of WAC (P = 2.29 × 10^{-11}). Both eQTLs were recently demonstrated in malignant plasma cells from EA patients.13,25 The recently identified association between rs4487645 at 7p5.13 and CDCA7L expression in EA patients23 was also evident at a borderline statistically significant level in malignant plasma cells from AA patients (P = 0.067). Of the 8 better AA MM markers, 3 showed nominally significant associations with gene expression that were not significant after correction for multiple testing: rs10180663 at 2p23.3 with HADHA, rs9290375 at 3q26.2 with GPR160, and rs879882 at 6p21.33 with VARS2 and HCG27.

We further explored the potential overlap between suggestive novel signals and their correlated SNPs (r^2 > 0.2, AFR population in 1KGP) with the genome regulatory domains and eQTL regions using the publicly available databases through HaploReg,26 UCSC Genome Browser,27 and GTex Portal.28 Neither of the 2 suggestive novel risk alleles showed overlap with regulatory elements. However, 2 correlated variants of rs13296848 (rs7854502, r^2 = 0.58; rs13285101, r^2 = 0.51; supplemental Figure 8) displayed enrichments in promoter and enhancer histone markers in multiple tissues,29 and both were associated with KN motif and ankyrin repeat domains 1 (KANK1) expression in Epstein-Barr virus–transformed lymphocytes, spleen, and whole blood.28

**Discussion**

In this largest genetic study of MM in individuals of AA, we did not identify any novel locus for MM risk. Of the 22 reported MM EA risk alleles that we were able to examine, 20 were directionally consistent and 9 achieved nominal statistical significance in AA individuals, suggesting a common shared underlying risk variant in these regions. Although most of the reported risk alleles had a modest association (OR < 1.2) with MM risk in AA individuals, in aggregate, we observed that those in the top 10% risk stratum had a 1.6- to 1.8-fold increase in MM risk compared with the population average risk (25th-75th percentile of the PRS distribution).

Overall, the effect sizes among persons of AAs were smaller than in the corresponding discovery reports among patients of EAs. The possible explanations for the smaller effect sizes include bias...
Table 1. The association between MM genetic risk regions identified in studies of EA and MM risk in 1813 patients and 8871 controls of AA

* r² was calculated among EUR/AFR populations in phase 3 1KGP. † RAFs were from the EUR population in phase 3 1KGP. ‡ ORs are from original GWAS reports. § RAFs are from AA controls. {AA MM ORs and Wald P values were adjusted for age, sex, and PCs 1-10. || P values of heterogeneity tests of fixed-effect meta-analyses. #Power was calculated using OR in the EA population, RAF in the AA population, and α = 0.05. **Index SNP in each risk region initially reported from GWAS studies of MM among EA populations. †† Better AA marker in each risk region that better captured AA MM risk.

14 JANUARY 2020 • VOLUME 4, NUMBER 1 MYELOMA GWASs IN AFRICAN AMERICANS 185
caused by “winner’s curse” in the EA discovery set, random errors from sampling across different studies, modification by environmental factors, and different linkage disequilibrium structure across ethnic groups between the index risk alleles and the functional causal SNPs. Although our study has sufficient statistical power (>80%) to replicate 18 of the risk alleles at a significance level of 0.05, more than half of them did not achieve nominal significance, implying that the index SNP in EA populations may not be a valid proxy for the causal variant in AA populations; thus, our fine-mapping of those risk regions in persons of AA was warranted.

Our previous study identified 5 better AA markers among 7 of the reported EA MM risk variants.9 Here, we identified better AA markers in 8 of the 22 regions that we examined. Our current study had greater power in characterizing AA MM risk variants as the result of improved imputation coverage by using the Haplotype Reference Consortium reference panel and increased AA sample size. Notably, we identified a better marker, rs10180663, in 2p23.3 with a much stronger association in the AA population than in our previous study.9 In this region, previous GWAS studies in the EA population have reported 2 MM risk variants, rs67460829 and rs7577599,11 and a pleotropic risk variant rs6546149 for B-cell malignancies, including chronic lymphocytic leukemia, Hodgkin lymphoma, and MM.30 Our better AA marker rs10180663 is correlated with all 3 of the aforementioned risk variants in the EA population ($r^2 > 0.25$ in EUR population in 1KGP) and displayed the strongest association among AA populations. Variant rs10180663 was also previously identified as a suggestive risk allele for the t(11;14)(q13;q32) MM molecular subtype among the EA population ($P = 2 \times 10^{-6}$).31 Moreover, it overlapped with H3K4Me1 enrichment in hematopoietic stem cells and B cells29 and was predicted to be located at an enhancer region,29

Figure 1. RAF of the 23 known risk alleles in 8871 unaffected controls of AA and in the EA population from the phase 3 1KGP.

Figure 2. Regional association plot of the 2p23.3 risk region (25.4-25.9 Mb) in persons of AA. SNPs are plotted by position (x-axis) and $-\log_{10} P$ value (y-axis). Linkage disequilibriums are estimated from the EUR population in phase 3 1KGP using $r^2$ statistics. The index SNP (bottom red arrow to purple circle) is rs6746082. The surrounding SNPs are colored to indicate pairwise correlation with the index SNP. The most associated SNP in the AA population in this region is rs10180663 (top red arrow).
suggesting that it might be a better surrogate for the causal MM variant in the 2p23.3 region in AA individuals.

Although no genome-wide novel variants were found, we did observe suggestive associations with rs13296848 located at 9p24.3, with a RAF of 0.33 among AA cases and a RAF of 0.28 among AA controls. This variant is located in the intron of the KANK1 gene, a candidate tumor suppressor for renal cell carcinoma.32 KANK1 may have a role in K9β-associated thrombocytopenia,33 which was found to be occasionally associated with MM.34 The correlated alleles of rs13296848 displayed enrichments in promoter and enhancer histone markers and were associated with KANK1 expression in Epstein-Barr virus–transformed lymphocytes, spleen, and whole blood.36 The other suggestive novel MM risk allele, rs7034061, was located at 19 kb 5′ of the gene insulin like growth factor binding protein 1 (IGFBP1), whose epigenetic inaction was reported as being involved in breast cancer pathogenesis.35 Moreover, serum fasting IGFBP1 concentration was associated with MM risk in a nested case-control study.36 However, no overlap of genome regulatory elements or IGFBP1 expression enrichment was detected for rs7034061 or its correlated SNPs in publicly available databases. Fine-mapping in larger samples of AA cases and controls is needed to determine whether this region harbors a true risk variant that is associated with MM risk.

Our study is the first to examine the association between local ancestry and MM risk. Compared with GWASs, admixture mapping has enhanced power (fewer tests requiring correction) but a lower resolution for discovering disease risk regions.37 We found that the level of local AA in a continuous region that covered the known risk region 2p23.3 was inversely associated with MM risk (P < 1 × 10⁻⁵). The signal could not be explained by the known risk marker rs6746082, but it was completely explained by conditioning on the 3 independent SNPs, including rs10180663. Thus, the previously noted signal in this region was detected in a different population using admixture mapping.

Unlike prostate cancer, in which variants at a single locus (8q24) were discovered by admixture mapping in men of AA,38 we did not identify a single locus that explains the excess risk for MM in AA individuals, although our study was well powered (80% power to detect a single locus with an OR of 1.7). It is possible that multiple loci with small effects, rather than a single region with a large effect, contribute to MM risk in AA individuals, which would require a much larger sample size than we have here. It is also possible that there is etiologic heterogeneity by molecular subtype and that, by combining them, we diluted the signal.

From the gene expression studies in malignant plasma cells from AA MM patients, the only risk variants that significantly impacted gene expression after correcting for multiple tests were rs2790457 at 10p12.1 (WAC) and rs1423269 at 5q15 (ELL2), 2 eQTLs that were recently shown in EA MM patients.11,26 The functional basis of the majority of MM risk variants remains elusive, and further studies, perhaps in circulating B-memory lymphocytes from healthy individuals, are required to understand the underlying biology.

A possible limitation of our study is that the AA MM cases and controls in Set 1 were genotyped on different platforms. To minimize this bias, we conducted stringent pre- and postimputation QC, including eliminating SNPs with low cross-platform replicate concordance and imputation to the same reference panel. There were only 188 376 genotyped SNPs overlapping between cases and controls in Set 1, because of the low density on the Illumina Human Core (298 930 SNPs) used for the cases. As a result, our imputation-based coverage of common variation was suboptimal for fine-mapping. A denser genotyping array may help to better localize causal variants in the AA population. In addition, given the low risk associated with these signals in some regions, a larger sample size is required to differentiate the causal variant from the index SNP. Moreover, because MM is characterized clinically by molecular subgroups,39 it is possible that genetic susceptibility may vary across these subtypes.12,31 The prevalence of each molecular subtype is <50%, and we did not have complete records of clinical molecular subtypes for all patients; thus, we could not evaluate subtype-specific associations. Although we had adequate power to examine most of the known risk variants at P < .05, the sample size was still not large enough for discovery of novel AA-specific genetic markers at a genome-wide significance level. Obtaining patient samples for such an uncommon cancer among a minority population is challenging. Nevertheless, this is the largest study in AA individuals to examine associations between common genetic variation and MM risk; our results show a role for genetic susceptibility in AA MM.
